The following table shows the immediate operand value for (V)CMPPD and (V)CMPPS.Some comparison operations that are not directly supported by immediate-byte encodings can be implemented by swapping the contents of the source and destination operands and executing the appropriate comparison of the swapped values. These additional comparison operations are shown with the directly supported comparison operations. The "^" operator in the table, like the XOR operator, toggles the value on the left if the value on the right is a '1'.

Immediate Operand Value	Compare Operation	Result If NaN Operand	QNaN Operand Causes Invalid Operation Exception
00h, 08h, 10h, 18h	Equal	FALSE ^ imm[3]	No ^ imm[4]
01h, 09h, 11h, 19h	Less than	FALSE ^ imm[3]	Yes ^ imm[4]
	Greater than (swapped operands)	FALSE ^ imm[3]	Yes ^ imm[4]
02h, 0Ah, 12h, 1Ah	Less than or equal	FALSE ^ imm[3]	Yes ^ imm[4]
	Greater than or equal (swapped operands)	FALSE ^ imm[3]	Yes ^ imm[4]
03h, 0Bh, 13h, 1Bh	Unordered	TRUE ^ imm[3]	No ^ imm[4]
04h, 0Ch, 14h, 1Ch	Not equal	TRUE ^ imm[3]	No ^ imm[4]
05h, 0Dh, 15h, 1Dh	Not less than	TRUE ^ imm[3]	Yes ^ imm[4]
	Not greater than (swapped operands)	TRUE ^ imm[3]	Yes ^ imm[4]
06h, 0Eh, 16h, 1Eh	Not less than or equal	TRUE ^ imm[3]	Yes ^ imm[4]
	Not greater than or equal (swapped operands)	TRUE ^ imm[3]	Yes ^ imm[4]
07h, 0Fh, 17h, 1Fh	Ordered	FALSE ^ imm[3]	No ^ imm[4]

The following alias mnemonics for (V)CMPPD with appropriate value of *imm8* are supported.

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

CMPPS Compare
VCMPPS Packed Single-Precision Floating-Point

Compares four, eight, or sixteen packed single-precision floating-point values of the first source operand to the corresponding values of the second source operand and writes the result of each comparison to the destination. The type of comparison is specified by an immediate byte operand.

Signed comparisons return TRUE only when both operands are valid numbers and the numbers have the relation specified by the type of comparison operation. Ordered and Unordered comparisons return a value based on the immediate byte. See “Immediate Operand Encoding” below.

QNaN operands generate an Invalid Operation Exception (IE) based on the immediate byte. See “Immediate Operand Encoding” below. SNaN operands always generate an IE.

There are legacy, VEX-encoded and EVEX-encoded forms of the instruction:

Legacy and VEX-encoded Forms

The destination is an XMM or a YMM register. When a comparison is TRUE, all 32 bits of the destination element are set; when a comparison is FALSE, all 32 bits of the destination element are cleared.

CMPPS

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected. Comparison type is specified by bits [2:0] of an immediate byte operand.

VCMPPS, VEX-Encoded Form

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared. Comparison type is specified by bits [4:0] of an immediate byte operand.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared Comparison type is specified by bits [4:0] of an immediate byte operand.

VCMPPS, EVEX-Encoded Form

The destination is a first mask register ‘k’, updated according to a second mask register ‘k1’. When a comparison is TRUE, the corresponding bit in the destination mask register is set to 1; when a comparison is FALSE, the result is 0. The EVEX form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

Memory fault suppression is supported.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or a broadcast 32-bit memory location. The destination is a mask register.

[AMD Public Use]

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or a broadcast 32-bit memory location. The destination is a mask register.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or a broadcast 32-bit memory location. The destination is a mask register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Immediate Operand Encoding

CMPPS uses only bits [2:0] of the 8-bit immediate operand and functions as if imm[4:3] are 00b. VCMPPS uses bits [4:0] of the 8-bit immediate operand.

(V)CMPPS uses immediate values similarly to the (V)CMPPD instruction. See the documentation on “(V)CMPPD Immediate Operand Encoding” on page 82.

The following alias mnemonics for (V)CMPPS with appropriate value of *imm8* are supported.

Mnemonic	Implied Value of *imm8*
(V)CMPEQPS	00h, 08h, 10h, 18h
(V)CMPLTPS	01h, 09h, 11h, 19h

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

CMPSD Compare
VCMPSD Scalar Double-Precision Floating-Point

Compares a double-precision floating-point value in the low-order 64 bits of the first source operand with a double-precision floating-point value in the low-order 64 bits of the second source operand and writes the result to the low-order bits of the destination. When a comparison is TRUE, bits of the destination element are set; when a comparison is FALSE, bits of the destination element are cleared. Comparison type is specified by an immediate byte operand.

Signed comparisons return TRUE only when both operands are valid numbers and the numbers have the relation specified by the type of comparison operation. Ordered comparison returns TRUE when both operands are valid numbers, or FALSE when either operand is a NaN. Unordered comparison returns TRUE only when one or both operands are NaN and FALSE otherwise.

QNaN operands generate an Invalid Operation Exception (IE) only when the comparison type is not Equal, Unequal, Ordered, or Unordered. SNaN operands always generate an IE.

There are legacy and extended forms of the instruction:

CMPSD

The first source operand is an XMM register. The second source operand is another XMM register or a 64-bit memory location. The first source register is also the destination. Bits [127:64] of the destination are not affected. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected. Bits [63:0] of the XMM destination are all set or all cleared based on the result of the comparison. Comparison type is specified by bits [2:0] of the immediate byte operand.

This CMPSD instruction must not be confused with the same-mnemonic CMPSD (compare strings by doubleword) instruction in the general-purpose instruction set. Assemblers can distinguish the instructions by the number and type of operands.

VCMPSD

The extended form of the instruction has two 128-bit encodings:

VEX Encoding

The first source operand is an XMM register. The second source operand is another XMM register or a 64-bit memory location. The destination is a third XMM register. Bits [127:64] of the destination are copied from bits [127:64] of the first source. Bits [512:128] of the ZMM/YMM register that corresponds to the destination are cleared. Bits [63:0] of the XMM destination are all set or all cleared based on the result of the comparison. Comparison type is specified by bits [4:0] of the immediate byte operand.

EVEX Encoding

The first source operand is an XMM register. The second source operand is another XMM register or a 64-bit memory location. The destination is a K mask register. Bits [63:1] of the destination are cleared. Bit [0] of the destination is set or cleared based on the result of the comparison. Comparison type is specified by bits [4:0] of the immediate byte operand. If a K mask register is specified in EVEX.aaa, bit 0 of that register will be used to mask the result with zero masking – the effect is to AND mask bit 0 with the comparison result before it is written to the destination.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

Immediate Operand Encoding

(V)CMPSD uses immediate values similarly to the (V)CMPPD instruction. See the documentation on “(V)CMPPD Immediate Operand Encoding” on page 82.

The following alias mnemonics for (V)CMPSD with appropriate value of *imm8* are supported.

Mnemonic	Implied Value of *imm8*

[AMD Public Use]

CMPSS Compare
VCMPSS Scalar Single-Precision Floating-Point

Compares a single-precision floating-point value in the low-order 32 bits of the first source operand with a single-precision floating-point value in the low-order 32 bits of the second source operand and writes the result to the low-order bits of the destination. When a comparison is TRUE, bits of the destination element are set; when a comparison is FALSE, bits of the destination element are cleared. Comparison type is specified by an immediate byte operand.

Signed comparisons return TRUE only when both operands are valid numbers and the numbers have the relation specified by the type of comparison operation. Ordered comparison returns TRUE when both operands are valid numbers, or FALSE when either operand is a NaN. Unordered comparison returns TRUE only when one or both operands are NaN and FALSE otherwise.

QNaN operands generate an Invalid Operation Exception (IE) only when the comparison type is not Equal, Unequal, Ordered, or Unordered. SNaN operands always generate an IE.

There are legacy and extended forms of the instruction:

CMPSS

The first source operand is an XMM register. The second source operand is another XMM register or a 32-bit memory location. The first source register is also the destination. Bits [127:32] of the destination are not affected. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected. Bits [31:0] of the XMM destination are all set or all cleared based on the result of the comparison. Comparison type is specified by bits [2:0] of the immediate byte operand.

VCMPSS

The extended form of the instruction has two 128-bit encodings.

VEX Encoding

The first source operand is an XMM register. The second source operand is another XMM register or a 32-bit memory location. The destination is a third XMM register. Bits [127:32] of the destination are copied from bits [127:32] of the first source. Bits [512:128] of the ZMM/YMM register that corresponds to the destination are cleared. Bits [31:0] of the XMM destination are all set or all cleared based on the result of the comparison. Comparison type is specified by bits [4:0] of the immediate byte operand.

EVEX Encoding

The first source operand is an XMM register. The second source operand is another XMM register or a 32-bit memory location. The destination is a K mask register. Bits [63:1] of the destination are cleared. Bit [0] of the destination is set or cleared based on the result of the comparison. Comparison type is specified by bits [4:0] of the immediate byte operand. If a K mask register is specified in EVEX.aaa, bit 0 of that register will be used to mask the result with zero masking - the effect is to AND mask bit 0 with the comparison result before it is written to the destination.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Immediate Operand Encoding

(V)CMPSS uses immediate values similarly to the (V)CMPPD instruction. See the documentation on “(V)CMPPD Immediate Operand Encoding” on page 82.

[AMD Public Use]

The following alias mnemonics for (V)CMPSS with appropriate value of *imm8* are supported.

Mnemonic	Implied Value of *imm8*

[AMD Public Use]

COMISD VCOMISD Compare Ordered Scalar Double-Precision Floating-Point

Compares a double-precision floating-point value in the low-order 64 bits of the first operand with a double-precision floating-point value in the low-order 64 bits of the second operand and sets rFLAGS.ZF, PF, and CF to show the result of the comparison:

Comparison	ZF	PF	CF
NaN input	1	1	1
operand 1 > operand 2	0	0	0
operand 1 < operand 2	0	0	1
operand 1 == operand 2	1	0	0

The result is unordered if one or both of the operand values is a NaN. The rFLAGS.OF, AF, and SF bits are cleared. If an #XF SIMD floating-point exception occurs the rFLAGS bits are not updated.

There are legacy and extended forms of the instruction:

COMISD

The first source operand is an XMM register. The second source operand is an XMM register or a 64-bit memory location.

VCOMISD

The extended form of the instruction has two128-bit encodings.

The first source operand is an XMM register. The second source operand is an XMM register or a 64-bit memory location.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Instruction Support

Form	Subset

COMISS VCOMISS Compare Ordered Scalar Single-Precision Floating-Point

Compares a single-precision floating-point value in the low-order 32 bits of the first operand with a single-precision floating-point value in the low-order 32 bits of the second operand and sets rFLAGS.ZF, PF, and CF to show the result of the comparison:

Comparison	ZF	PF	CF
NaN input	1	1	1
operand 1 > operand 2	0	0	0
operand 1 < operand 2	0	0	1
operand 1 == operand 2	1	0	0

The result is unordered if one or both of the operand values is a NaN. The rFLAGS.OF, AF, and SF bits are cleared. If an #XF SIMD floating-point exception occurs the rFLAGS bits are not updated.

There are legacy and extended forms of the instruction:

COMISS

The first source operand is an XMM register. The second source operand is an XMM register or a 32-bit memory location.

VCOMISS

The extended form of the instruction has two 128-bit encodings.

The first source operand is an XMM register. The second source operand is an XMM register or a 32-bit memory location.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

CVTDQ2PD VCVTDQ2PD Convert Packed Doubleword Integers to Packed Double-Precision Floating-Point

Converts packed 32-bit signed integer values to packed double-precision floating-point values and writes the converted values to the destination.

There are legacy and extended forms of the instruction:

CVTDQ2PD

Converts two packed 32-bit signed integer values in the low-order 64 bits of an XMM register or in a 64-bit memory location to two packed double-precision floating-point values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VCVTDQ2PD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts two packed 32-bit signed integer values in the low-order 64 bits of an XMM register, in a 64-bit memory location to two packed double-precision floating-point values, or (for EVEX encodings) a broadcast 32-bit memory location and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts four packed 32-bit signed integer values in the low-order 128 bits of a YMM register, a 256-bit memory location to four packed double-precision floating-point values, or (for EVEX encodings) a broadcast 32-bit memory location and writes the converted values to a YMM register. Bits above bit 255 of the YMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts eight packed 32-bit signed integer values in a ZMM register or a 512-bit memory location to sixteen packed double-precision floating-point values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression. Note that these EVEX instructions encodings allow for {er} to be specified, even when no rounding is done. It is recommended that {er} not be specified under these circumstances since different assemblers may or may not allow {er} when it is unused.

Instruction Support

CVTDQ2PS VCVTDQ2PS Convert Packed Doubleword Integers to Packed Single-Precision Floating-Point

Converts packed 32-bit signed integer values to packed single-precision floating-point values and writes the converted values to the destination. When the result is an inexact value, it is rounded as specified by MXCSR.RC.

There are legacy and extended forms of the instruction:

CVTDQ2PS

Converts four packed 32-bit signed integer values in an XMM register, a 128-bit memory location to four packed single-precision floating-point values and writes the converted values to an XMM register. Bits above 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VCVTDQ2PS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts four packed 32-bit signed integer values in an XMM register, a 128-bit memory location to four packed single-precision floating-point values, or (for EVEX encodings) a broadcast 32-bit memory location and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts eight packed 32-bit signed integer values in a YMM register, a 256-bit memory location to eight single-precision floating-point values, or (for EVEX encodings) a broadcast 32-bit memory location and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts sixteen packed 32-bit signed integer values in a ZMM register or a 512-bit memory location to sixteen packed single-precision floating-point values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

CVTPD2DQ VCVTPD2DQ Convert Packed Double-Precision Floating-Point to Packed Doubleword Integer

Converts packed double-precision floating-point values to packed signed doubleword integers and writes the converted values to the destination. When the result is an inexact value, it is rounded as specified by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTPD2DQ

Converts two packed double-precision floating-point values in an XMM register or a 128-bit memory location to two packed signed doubleword integers and writes the converted values to the two low-order doublewords of the destination XMM register. Bits [127:64] of the destination are cleared. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VCVTPD2DQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts two packed double-precision floating-point values in an XMM register, a 128-bit memory location to two signed doubleword values, or (for EVEX encodings) a broadcast 64-bit memory location and writes the converted values to the lower two doubleword elements of the destination XMM register. Bits [127:64] of the destination are cleared. Bits above bit 127 of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts four packed double-precision floating-point values in a YMM register, a 256-bit memory location to four signed doubleword values, or (for EVEX encodings) a broadcast 64-bit memory location. and writes the converted values to an XMM register. Bits [511:128] of the XMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts eight packed 32-bit double-precision floating-point values in a ZMM register or a 512-bit memory location to sixteen signed doubleword values and writes the converted values to a ZMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

CVTPD2PS Convert Packed Double-Precision Floating-Point
VCVTPD2PS to Packed Single-Precision Floating-Point

Converts packed double-precision floating-point values to packed single-precision floating-point values and writes the converted values to the low-order doubleword elements of the destination. When the result is an inexact value, it is rounded as specified by MXCSR.RC.

There are legacy and extended forms of the instruction:

CVTPD2PS

Converts two packed double-precision floating-point values in an XMM register or a 128-bit memory location to two packed single-precision floating-point values, and writes the converted values to an XMM register. Bits [127:64] of the destination are cleared. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VCVTPD2PS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts two packed double-precision floating-point values in an XMM register, a 128-bit memory location to two packed single-precision floating-point values, or (for EVEX encodings) a broadcast 64-bit memory location and writes the converted values to an XMM register. Bits [127:64] of the destination are cleared. Bits above bit 127 of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts four packed double-precision floating-point values in a YMM register, a 256-bit memory location to four packed single-precision floating-point values, or (for EVEX encodings) a broadcast 64-bit memory location and writes the converted values to a YMM register. Bits [511:128] of the YMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts eight packed 32-bit double-precision floating-point values in a ZMM register or a 512-bit memory location to sixteen packed single-precision floating-point values and writes the converted values to a ZMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

CVTPS2DQ VCVTPS2DQ Convert Packed Single-Precision Floating-Point to Packed Doubleword Integers

Converts packed single-precision floating-point values to packed signed doubleword integer values and writes the converted values to the destination.

When the result is an inexact value, it is rounded as specified by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTPS2DQ

Converts four packed single-precision floating-point values in an XMM register or a 128-bit memory location to four packed signed doubleword integer values and writes the converted values to an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VCVTPS2DQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts four packed single-precision floating-point values in an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to four packed signed doubleword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts eight packed single-precision floating-point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory locationto eight packed signed doubleword integer values and writes the converted values to a YMM register. Bitsabove bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts sixteen packed 32-bit signed integer values in a ZMM register or a 512-bit memory location to sixteen packed signed doubleword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

CVTPS2PD VCVTPS2PD Convert Packed Single-Precision Floating-Point to Packed Double-Precision Floating-Point

Converts packed single-precision floating-point values to packed double-precision floating-point values and writes the converted values to the destination.

There are legacy and extended forms of the instruction:

CVTPS2PD

Converts two packed single-precision floating-point values in the two low order doubleword elements of an XMM register or a 64-bit memory location to two double-precision floating-point values and writes the converted values to an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VCVTPS2PD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts two packed single-precision floating-point values in the two low order doubleword elements of an XMM register, a 64-bit memory location to two double-precision floating-point values, or (for EVEX encodings) a broadcast 32-bit memory location and writes the converted values to an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts four packed single-precision floating-point values in a YMM register, a 128-bit memory location to four double-precision floating-point values, or (for EVEX encodings) a broadcast 32-bit memory location and writes the converted values to a YMM register. Bits above bit 255 of the YMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts eight packed 32-bit packed single-precision floating-pointr values in a ZMM register or a 512-bit memory location to sixteen packed double-precision floating-point values and writes the converted values to a ZMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

CVTSD2SI VCVTSD2SI Convert Scalar Double-Precision Floating-Point to Signed Doubleword or Quadword Integer

Converts a scalar double-precision floating-point value to a 32-bit or 64-bit signed integer value and writes the converted value to a general-purpose register.

When the result is an inexact value, it is rounded as specified by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$) or quadword value (-2^{63} to $+2^{63} - 1$), the instruction returns the indefinite integer value (8000_0000h for 32-bit integers, 8000_0000_0000_0000h for 64-bit integers) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTSD2SI

The legacy form has two encodings.

- In non-64-bit modes, or in 64-bit mode when REX.W = 0, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 32-bit signed integer and writes the converted value to a 32-bit general purpose register.
- In 64-bit mode, when REX.W = 1, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 64-bit sign-extended integer and writes the converted value to a 64-bit general purpose register.

VCVTSD2SI

The extended form of the instruction has two 128-bit encodings.

- In non-64-bit modes, or in 64-bit mode when (E)VEX.W = 0, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 32-bit signed integer and writes the converted value to a 32-bit general purpose register.
- In 64-bit mode when (E)VEX.W = 1, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 64-bit sign-extended integer and writes the converted value to a 64-bit general purpose register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

CVTSD2SS VCVTSD2SS Convert Scalar Double-Precision Floating-Point to Scalar Single-Precision Floating-Point

Converts a scalar double-precision floating-point value to a scalar single-precision floating-point value and writes the converted value to the low-order 32 bits of the destination. When the result is an inexact value, it is rounded as specified by MXCSR.RC.

There are legacy and extended forms of the instruction:

CVTSD2SS

Converts a scalar double-precision floating-point value in the low-order 64 bits of the second source XMM register or a 64-bit memory location to a scalar single-precision floating-point value and writes the converted value to the low-order 32 bits of a destination XMM register. Bits [127:32] of the destination are not affected. Bits [511:128] of the ZMM/YMM register that corresponds to the destination are not affected.

VCVTSD2SS

The extended form of the instruction has a 128-bit encoding only.

Converts a scalar double-precision floating-point value in the low-order 64 bits of a source XMM register or a 64-bit memory location to a scalar single-precision floating-point value and writes the converted value to the low-order 32 bits of the destination XMM register. For EVEX encodings, the value is written only if the k mask register bit 0 is a ‘1.’ Bits [127:32] of the destination are copied from the first source XMM register. Bits [511:128] of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

CVTSI2SD VCVTSI2SD Convert Signed Doubleword or Quadword Integer to Scalar Double-Precision Floating-Point

Converts a signed integer value to a double-precision floating-point value and writes the converted value to a destination register. When the result of the conversion is an inexact value, the value is rounded as specified by MXCSR.RC.

There are legacy and extended forms of the instruction:

CVTSI2SD

The legacy form as two encodings.

- In non-64-bit modes, or in 64-bit mode when REX.W = 0, converts a signed doubleword integer value from a 32-bit source general-purpose register or a 32-bit memory location to a double-precision floating-point value and writes the converted value to the low-order 64 bits of an XMM register. Bits [127:64] of the destination XMM register and bits above 127 of the corresponding YMM register are not affected.
- In 64-bit mode, when REX.W = 1, converts a signed quadword integer value from a 64-bit source general-purpose register or a 64-bit memory location to a 64-bit double-precision floating-point value and writes the converted value to the low-order 64 bits of an XMM register. Bits [127:64] of the destination XMM register and bits above 127 of the corresponding YMM register are not affected.

VCVTSI2SD

The extended form of the instruction has two 128-bit encodings.

- In non-64-bit modes, or in 64-bit mode when (E)VEX.W = 0, converts a signed doubleword integer value from a 32-bit source general-purpose register or a 32-bit memory location to a double-precision floating-point value and writes the converted value to the low-order 64 bits of the destination XMM register. Bits [127:64] of the first source XMM register are copied to the destination XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.
- In 64-bit mode when (E)VEX.W = 1, converts a signed quadword integer value from a 64-bit source general-purpose register or a 64-bit memory location to a double-precision floating-point value and writes the converted value to the low-order 64 bits of the destination XMM register. Bits [127:64] of the first source XMM register are copied to the destination XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression. Note that these EVEX instructions encodings allow for {er} to be specified, even when no rounding is done. It is recommended that {er} not be specified under these circumstances since different assemblers may or may not allow {er} when it is unused.

CVTSI2SS VCVTSI2SS Convert Signed Doubleword or Quadword Integer to Scalar Single-Precision Floating-Point

Converts a signed integer value to a single-precision floating-point value and writes the converted value to an XMM register. When the result of the conversion is an inexact value, the value is rounded as specified by MXCSR.RC.

There are legacy and extended forms of the instruction:

CVTSI2SS

The legacy form has two encodings.

- In non-64-bit modes, or in 64-bit mode when REX.W = 0, converts a signed doubleword integer value from a 32-bit source general-purpose register or a 32-bit memory location to a single-precision floating-point value and writes the converted value to the low-order 32 bits of an XMM register. Bits [127:32] of the destination XMM register and bits above 127 of the corresponding YMM register are not affected.
- In 64-bit mode, when REX.W = 1, converts a signed quadword integer value from a 64-bit source general-purpose register or a 64-bit memory location to a single-precision floating-point value and writes the converted value to the low-order 32 bits of an XMM register. Bits [127:32] of the destination XMM register and bits above 127 of the corresponding YMM register are not affected.

VCVTSI2SS

The extended form of the instruction has two 128-bit encodings.

- In non-64-bit modes, or in 64-bit mode when (E)VEX.W = 0, converts a signed doubleword integer value from a 32-bit source general-purpose register or a 32-bit memory location to a single-precision floating-point value and writes the converted value to the low-order 32 bits of the destination XMM register. Bits [127:32] of the first source XMM register are copied to the destination XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.
- In 64-bit mode when (E)VEX.W = 1, converts a signed quadword integer value from a 64-bit source general-purpose register or a 64-bit memory location to a single-precision floating-point value and writes the converted value to the low-order 32 bits of the destination XMM register. Bits [127:32] of the first source XMM register are copied to the destination XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

CVTSS2SD VCVTSS2SD Convert Scalar Single-Precision Floating-Point to Scalar Double-Precision Floating-Point

Converts a scalar single-precision floating-point value to a scalar double-precision floating-point value and writes the converted value to the low-order 64 bits of the destination.

There are legacy and extended forms of the instruction:

CVTSS2SD

Converts a scalar single-precision floating-point value in the low-order 32 bits of a source XMM register or a 32-bit memory location to a scalar double-precision floating-point value and writes the converted value to the low-order 64 bits of a destination XMM register. Bits [127:64] of the destination and bits [511:128] of the corresponding ZMM/YMM register are not affected.

VCVTSS2SD

The extended form of the instruction has a 128-bit encoding only.

Converts a scalar single-precision floating-point value in the low-order 32 bits of the second source XMM register or 32-bit memory location to a scalar double-precision floating-point value and writes the converted value to the low-order 64 bits of the destination XMM register. For EVEX encodings, the value is written only if the k mask register bit 0 is a ‘1.’ Bits [127:64] of the destination are copied from the first source XMM register. Bits [511:128] of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Instruction Support

Form	Subset
CVTSS2SD	SSE2
VEX VCVTSS2SD	AVX
EVEX VCVTSS2SD	AVX512F

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

CVTSS2SI VCVTSS2SI Convert Scalar Single-Precision Floating-Point to Signed Doubleword or Quadword Integer

Converts a single-precision floating-point value to a signed integer value and writes the converted value to a general-purpose register.

When the result of the conversion is an inexact value, the value is rounded as specified by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$) or quadword value (-2^{63} to $+2^{63} - 1$), the indefinite integer value (8000_0000h for 32-bit integers, 8000_0000_0000_0000h for 64-bit integers) is returned when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTSS2SI

The legacy form has two encodings.

- In non-64-bit modes, or in 64-bit mode when REX.W = 0, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 32-bit signed integer value and writes the converted value to a 32-bit general-purpose register.
- In 64-bit mode, when REX.W = 1, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 64-bit signed integer value and writes the converted value to a 64-bit general-purpose register.

VCVTSS2SI

The extended form of the instruction has two 128-bit encodings.

- In non-64-bit modes, or in 64-bit mode when (E)VEX.W = 0, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 32-bit signed integer value and writes the converted value to a 32-bit general-purpose register.
- In 64-bit mode when (E)VEX.W = 1, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 64-bit signed integer value and writes the converted value to a 64-bit general-purpose register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Instruction Support

Form	Subset
CVTSS2SI	SSE
VEX VCVTSS2SI	AVX
EVEX VCVTSS2SI	AVX512F

CVTTPD2DQ Convert Packed Double-Precision Floating-Point
VCVTTPD2DQ to Packed Doubleword Integer, Truncated

Converts packed double-precision floating-point values to packed signed doubleword integer values and writes the converted values to the destination. When the result is an inexact value, it is truncated (rounded toward zero). When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTTPD2DQ

Converts two packed double-precision floating-point values in an XMM register or a 128-bit memory location to two packed signed doubleword integers and writes the converted values to the two low-order doublewords of the destination XMM register. Bits [127:64] of the destination are cleared. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VCVTTPD2DQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts two packed double-precision floating-point values in an XMM register, a 128-bit memory location to two signed doubleword values, or (for EVEX encodings) a broadcast 64-bit memory location and writes the converted values to the lower two doubleword elements of the destination XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts four packed double-precision floating-point values in a YMM register, a 256-bit memory location to four signed doubleword integer values, or (for EVEX encodings) a broadcast 64-bit memory location and writes the converted values to an XMM register. Bits [511:128] of the XMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts eight packed double-precision floating-point values in a ZMM register or a 512-bit memory location to eight signed doubleword integer values and writes the converted values to a ZMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

CVTTPS2DQ VCVTTPS2DQ Convert Packed Single-Precision Floating-Point to Packed Doubleword Integers, Truncated

Converts packed single-precision floating-point values to packed signed doubleword integer values and writes the converted values to the destination.

When the result of the conversion is an inexact value, the value is truncated (rounded toward zero). When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTTPS2DQ

Converts four packed single-precision floating-point values in an XMM register or a 128-bit memory location to four packed signed doubleword integer values and writes the converted values to an XMM register. The high-order 128-bits of the corresponding YMM register are not affected.

VCVTTPS2DQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts four packed single-precision floating-point values in an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory locationto four packed signed doubleword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts eight packed single-precision floating-point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory locationto eight packed signed doubleword integer values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts sixteen packed single-precision floating point values in a ZMM register, or a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to sixteen packed double-precision floating-point values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

CVTTSD2SI Convert Scalar Double-Precision Floating-Point VCVTTSD2SI to Signed Double- or Quadword Integer, Truncated

Converts a scalar double-precision floating-point value to a signed integer value and writes the converted value to a general-purpose register.

When the result of the conversion is an inexact value, the value is truncated (rounded toward zero). When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$) or quadword value (-2^{63} to $+2^{63} - 1$), the instruction returns the indefinite integer value (8000_0000h for 32-bit integers, 8000_0000_0000_0000h for 64-bit integers) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTTSD2SI

The legacy form of the instruction has two encodings.

- In non-64-bit modes, or in 64-bit mode when REX.W = 0, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 32-bit signed integer and writes the converted value to a 32-bit general purpose register.
- In 64-bit mode, when REX.W = 1, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 64-bit sign-extended integer and writes the converted value to a 64-bit general purpose register.

VCVTTSD2SI

The extended form of the instruction has two 128-bit encodings.

- In non-64-bit modes, or in 64-bit mode when (E)VEX.W = 0, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 32-bit signed integer and writes the converted value to a 32-bit general purpose register.
- In 64-bit mode when (E)VEX.W = 1, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 64-bit sign-extended integer and writes the converted value to a 64-bit general purpose register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

CVTTSS2SI Convert Scalar Single-Precision Floating-Point VCVTTSS2SI to Signed Double or Quadword Integer, Truncated

Converts a single-precision floating-point value to a signed integer value and writes the converted value to a general-purpose register.

When the result of the conversion is an inexact value, the value is truncated (rounded toward zero). When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$) or quadword value (-2^{63} to $+2^{63} - 1$), the indefinite integer value (8000_0000h for 32-bit integers, 8000_0000_0000_0000h for 64-bit integers) is returned when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTTSS2SI

The legacy form of the instruction has two encodings.

- In non-64-bit modes, or in 64-bit mode when REX.W = 0, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 32-bit signed integer value and writes the converted value to a 32-bit general-purpose register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.
- In 64-bit mode, when REX.W = 1, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 64-bit signed integer value and writes the converted value to a 64-bit general-purpose register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VCVTTSS2SI

The extended form of the instruction has two 128-bit encodings.

- In non-64-bit modes, or in 64-bit mode when (E)VEX.W = 0, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 32-bit signed integer value and writes the converted value to a 32-bit general-purpose register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.
- In 64-bit mode when (E)VEX.W = 1, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 64-bit signed integer value and writes the converted value to a 64-bit general-purpose register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

DIVPD VDIVPD Divide Packed Double-Precision Floating-Point

Divides four, eight, or sixteen packed double-precision floating-point values of the first source operand by the corresponding packed double-precision floating-point value of the second source operand and writes the quotient of each division into the corresponding quadword of the destination.

There are legacy and extended forms of the instruction:

DIVPD

Divides two pairs of values.

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VDIVPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Divides two pairs of values.

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Divides four pairs of values.

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Divides eight pairs of values.

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

DIVSD Divide
VDIVSD Scalar Double-Precision Floating-Point

Divides the double-precision floating-point value in the low-order quadword of the first source operand by the corresponding value in the low-order quadword of the second source operand and writes the result into the low-order quadword of the destination.

There are legacy and extended forms of the instruction:

DIVSD

The first source operand is an XMM register. The second source operand is an XMM register or a 64-bit memory location. The first source register is also the destination. Bits [127:64] of the destination are not affected. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VDIVSD

The extended forms of the instruction have 128-bit encodings only.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 64-bit memory location. The destination is a third XMM register. Bits [127:64] of the first source operand are copied to bits [127:64] of the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Instruction Support

Form	Subset
DIVSD	SSE2
VEX VDIVSD	AVX
EVEX VDIVSD	AVX512F

DPPD VDPPD Dot Product Packed Double-Precision Floating-Point

Computes the dot-product of the input operands. An immediate operand specifies both the input values and the destination locations to which the products are written.

Selectively multiplies packed double-precision values in a source operand by the corresponding values in a second source operand, writes the results to a temporary location, adds the results, writes the sum to a second temporary location and selectively writes the sum to a destination.

Mask bits [5:4] of an 8-bit immediate operand perform multiplicative selection. Bit 5 selects bits [127:64] of the source operands; bit 4 selects bits [63:0] of the source operands. When a mask bit = 1, the corresponding packed double-precision floating point values are multiplied and the product is written to the corresponding position of a 128-bit temporary location. When a mask bit = 0, the corresponding position of the temporary location is cleared.

After the two 64-bit values in the first temporary location are added and written to the 64-bit second temporary location, mask bits [1:0] of the same 8-bit immediate operand perform write selection. Bit 1 selects bits [127:64] of the destination; bit 0 selects bits [63:0] of the destination. When a mask bit = 1, the 64-bit value of the second temporary location is written to the corresponding position of the destination. When a mask bit = 0, the corresponding position of the destination is cleared.

When the operation produces a NaN, its value is determined as follows.

Source Operands (in either order)		NaN Result[1]
QNaN	Any non-NaN floating-point value (or single-operand instruction)	Value of QNaN
SNaN	Any non-NaN floating-point value (or single-operand instruction)	Value of SNaN, converted to a QNaN[2]
QNaN	QNaN	First operand
QNaN	SNaN	First operand (converted to QNaN if SNaN
SNaN	SNaN	First operand converted to a QNaN[2]

Note: *1. A NaN result produced when the floating-point invalid-operation exception is masked.*
2. The conversion is done by changing the most-significant fraction bit to 1.

For each addition occurring in either the second or third step, for the purpose of NaN propagation, the addend of lower bit index is considered to be the first of the two operands. For example, when both multiplications produce NaNs, the one that corresponds to bits [64:0] is written to all indicated fields of the destination, regardless of how those NaNs were generated from the sources. When the high-order multiplication produces NaNs and the low-order multiplication produces infinities of opposite signs, the real indefinite QNaN (produced as the sum of the infinities) is written to the destination.

NaNs in source operands or in computational results result in at least one NaN in the destination. For the 256-bit version, NaNs are propagated within the two independent dot product operations only to their respective 128-bit results.

[AMD Public Use]

There are legacy and extended forms of the instruction:

DPPD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VDPPD

The extended form of the instruction has a single 128-bit encoding. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

DPPS Dot Product
VDPPS Packed Single-Precision Floating-Point

Computes the dot-product of the input operands. An immediate operand specifies both the input values and the destination locations to which the products are written.

Selectively multiplies packed single-precision values in a source operand by corresponding values in a second source operand, writes results to a temporary location, adds pairs of results, writes the sums to additional temporary locations, and selectively writes a cumulative sum to a destination.

Mask bits [7:4] of an 8-bit immediate operand perform multiplicative selection. Each bit selects a 32-bit segment of the source operands; bit 7 selects bits [127:96], bit 6 selects bits [95:64], bit 5 selects bits [63:32], and bit 4 selects bits [31:0]. When a mask bit = 1, the corresponding packed single-precision floating point values are multiplied and the product is written to the corresponding position of a 128-bit temporary location. When a mask bit = 0, the corresponding position of the temporary location is cleared.

After multiplication, three pairs of 32-bit values are added and written to temporary locations. Bits [63:32] and [31:0] of temporary location 1 are added and written to 32-bit temporary location 2; bits [127:96] and [95:64] of temporary location 1 are added and written to 32-bit temporary location 3; then the contents of temporary locations 2 and 3 are added and written to 32-bit temporary location 4.

After addition, mask bits [3:0] of the same 8-bit immediate operand perform write selection. Each bit selects a 32-bit segment of the source operands; bit 3 selects bits [127:96], bit 2 selects bits [95:64], bit 1 selects bits [63:32], and bit 0 selects bits [31:0] of the destination. When a mask bit = 1, the 64-bit value of the fourth temporary location is written to the corresponding position of the destination. When a mask bit = 0, the corresponding position of the destination is cleared.

For the 256-bit extended encoding, this process is performed on the upper and lower 128 bits of the affected YMM registers.

When the operation produces a NaN, its value is determined as follows.

Source Operands (in either order)		NaN Result[1]
QNaN	Any non-NaN floating-point value (or single-operand instruction)	Value of QNaN
SNaN	Any non-NaN floating-point value (or single-operand instruction)	Value of SNaN, converted to a QNaN[2]
QNaN	QNaN	First operand
QNaN	SNaN	First operand (converted to QNaN if SNaN
SNaN	SNaN	First operand converted to a QNaN[2]

Note: *1. A NaN result produced when the floating-point invalid-operation exception is masked.*
2. The conversion is done by changing the most-significant fraction bit to 1.

For each addition occurring in either the second or third step, for the purpose of NaN propagation, the addend of lower bit index is considered to be the first of the two operands. For example, when all four multiplications produce NaNs, the one that corresponds to bits [31:0] is written to all indicated fields of the destination, regardless of how those NaNs were generated from the sources. When the two

[AMD Public Use]

highest-order multiplication produce NaNs and the two lowest-low-order multiplications produce infinities of opposite signs, the real indefinite QNaN (produced as the sum of the infinities) is written to the destination.

NaNs in source operands or in computational results result in at least one NaN in the destination. For the 256-bit version, NaNs are propagated within the two independent dot product operations only to their respective 128-bit results.

There are legacy and extended forms of the instruction:

DPPS

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VDPPS

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register.

[AMD Public Use]

EXTRACTPS Extract
VEXTRACTPS Packed Single-Precision Floating-Point

Copies one of four packed single-precision floating-point values from a source XMM register to a general purpose register or a 32-bit memory location. Bits [1:0] of an immediate byte operand specify the location of the 32-bit value that is copied. 00b corresponds to the low word of the source register and 11b corresponds to the high word of the source register. Bits [7:2] of the immediate operand are ignored.

There are legacy and extended forms of the instruction:

EXTRACTPS

The source operand is an XMM register. The destination can be a general-purpose register or a 32-bit memory location. A 32-bit single-precision value extracted to a general-purpose register is zero-extended to 64-bits.

VEXTRACTPS

The extended form of the instruction has a single 128-bit encoding. The source operand is an XMM register. The destination can be a general-purpose register or a 32-bit memory location.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

EXTRQ Extract Field From Register

Extracts specified bits from the lower 64 bits of the first operand (the destination XMM register). The extracted bits are saved in the least-significant bit positions of the lower quadword of the destination; the remaining bits in the lower quadword of the destination register are cleared to 0. The upper quadword of the destination register is undefined.

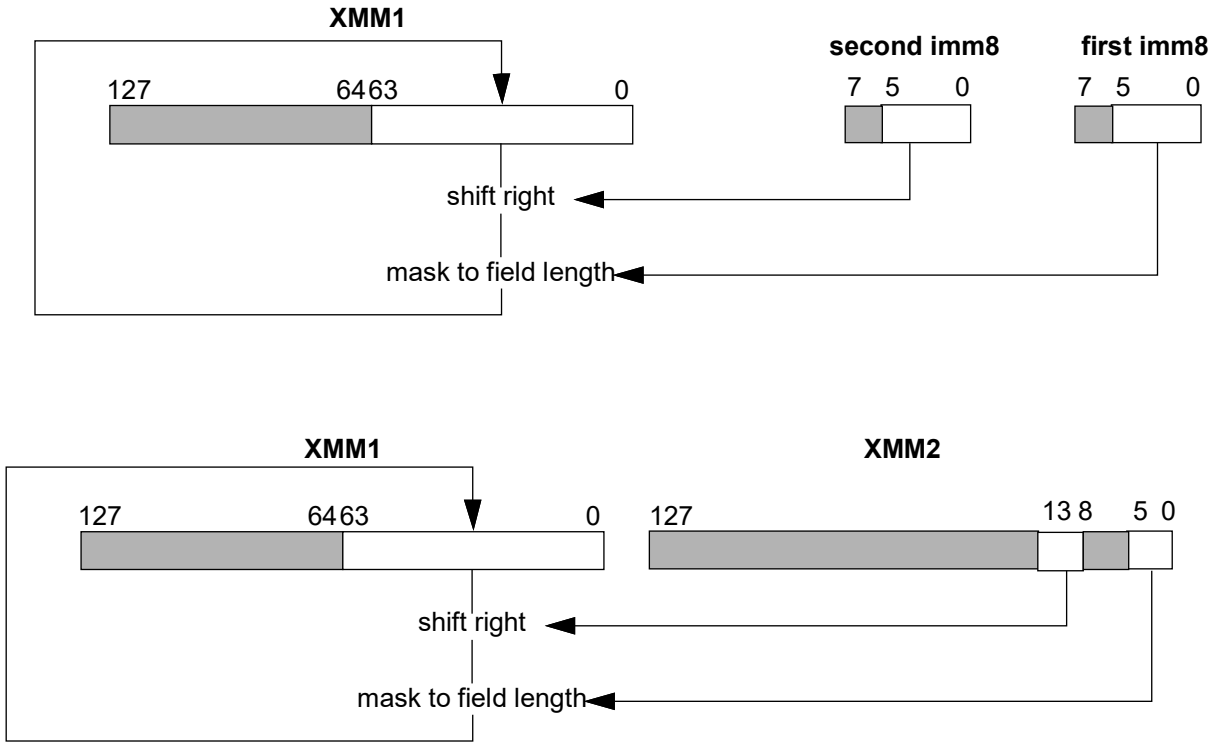
The portion of the source data being extracted is defined by the bit index and the field length. The bit index defines the least-significant bit of the source operand being extracted. Bits [*bit index* + *length field* – 1]:[*bit index*] are extracted. If the sum of the *bit index* + *length field* is greater than 64, the results are undefined.

For example, if the bit index is 32 (20h) and the field length is 16 (10h), then the result in the destination register will be source [47:32] in bits 15:0, with zeros in bits 63:16.

A value of zero in the field length is defined as a length of 64. If the *length field* is 0 and the *bit index* is 0, bits 63:0 of the source are extracted. For any other value of the *bit index*, the results are undefined.

The *bit index* and *field length* can be specified as immediate values (second and first immediate operands, respectively, in the case of the three argument version of the instruction), or they can both be specified by fields in an XMM source operand. In the latter case, bits [5:0] of the XMM register specify the number of bits to extract (the *field length*) and bits [13:8] of the XMM register specify the index of the first bit in the field to extract. The *bit index* and *field length* are each six bits in length; other bits of the field are ignored.

The diagram below illustrates the operation of this instruction.



[AMD Public Use]

GF2P8AFFINEINVQB VGF2P8AFFINEINVQB — Perform a Galois Inverse Affine Transformation

Perform a Galois inverse affine transformation on 64-bit qword blocks of byte data.

Each bit (bit_n) in each byte (byte_n) in each result 64-bit block is a function of the two corresponding 64-bit source blocks in source operands 1 and 2 (src1blk, src2blk) and the immediate byte (imm8):

result.byte[byte_n].bit[bit_n] = odd_parity(src2blk.byte[7-bit_n] & inverse(src1blk.byte[byte_n])) ^ imm8.bit[bit_n]

The odd_parity() function is defined as 1 if the input byte has an odd number of 1 bits in it, and 0 otherwise.

The inverse() function takes a byte as input and returns the byte from the following hexadecimal table as output:

Input Byte [7:4]		Input Byte [3:0]															
		_0	_1	_2	_3	_4	_5	_6	_7	_8	_9	_A	_B	-C	_D	_E	_F

There are legacy and extended forms of this instruction:

GF2P8AFFINEINVQB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VGF2P8AFFINEINVQB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

[AMD Public Use]

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and do not support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

GF2P8MULB VGF2P8MULB Multiply Byte Elements of a Finite Field

Perform a multiply on a finite field byte data.

Each byte in the result is a function of the two corresponding source bytes in source operands 1 and 2:

For each byte (byte_n) in the sources/destinations (16, 32, or 64 bytes):

```
result.byte[byte_n] = poly11b_reduce(xor_mul(src2.byte[byte_n], src1.byte[byte_n]))
```

The xor_mul() function takes 2 byte inputs and returns a word value. It is like a normal multiply except the partial products are XORed instead of added. The result word is calculated as follows:

```
result_word = 0
 For each bit (bit_n) from 0 to 7:
  if src2byte.bit(bit_n) == 1:
   result_word = result_word XOR (src1byte << bit_n)
 return(result_word)
```

The poly11b_reduce() function takes a data word and returns a byte which is the input data word reduced by the polynomial x^8 + x^4 + x^3 + x^1 + x^0 (represented by hex value 0x011b). The input data word is reduced by the polynomial as follows:

```
data_word = input data word
 For each bit (bit_n) from 14 to 8:
  if data_word.bit[bit_n] == 1:
   data_word = data_word XOR (0x011b << (bit_n - 8))
 return(data_word.byte[0]) // Note that bits above bit 7 in data_word will all be 0
```

There are legacy and extended forms of this instruction:

GF2P8MULB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VGF2P8MULB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

[AMD Public Use]

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

HADDPS
VHADDPS — Horizontal Add Packed Single-Precision

Adds adjacent pairs of single-precision floating-point values in two source operands and writes the sums to a destination.

There are legacy and extended forms of the instruction:

HADDPS

Adds the packed single-precision values in bits [63:32] and bits [31:0] of the first source XMM register and writes the sum to bits [31:0] of the destination; adds the packed single-precision values in bits [127:96] and bits [95:64] of the first source register and writes the sum to bits [63:32] of the destination. Adds the corresponding values in the second source XMM register or a 128-bit memory location and writes the sum to bits [95:64] and [127:96] of the destination. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VHADDPS

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Adds the packed single-precision values in bits [63:32] and bits [31:0] of the first source XMM register and writes the sum to bits [31:0] of the destination XMM register; adds the packed single-precision values in bits [127:96] and bits [95:64] of the first source register and writes the sum to bits [63:32] of the destination. Adds the corresponding values in the second source XMM register or a 128-bit memory location and writes the sum to bits [95:64] and [127:96] of the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Adds the packed single-precision values in bits [63:32] and bits [31:0] of the first source YMM register and writes the sum to bits [31:0] of the destination YMM register; adds the packed single-precision values in bits [127:96] and bits [95:64] of the first source register and writes the sum to bits [63:32] of the destination. Adds the corresponding values in the second source YMM register or a 256-bit memory location and writes the sums to bits [95:64] and [127:96] of the destination. Performs the same process for the upper 128 bits of the sources and destination.

[AMD Public Use]

HSUBPD VHSUBPD Horizontal Subtract Packed Double-Precision

Subtracts adjacent pairs of double-precision floating-point values in two source operands and writes the sums to a destination.

There are legacy and extended forms of the instruction:

HSUBPD

The first source register is also the destination.

Subtracts the packed double-precision value in bits [127:64] from the value in bits [63:0] of the first source XMM register and writes the difference to bits [63:0] of the destination; subtracts the corresponding values of the second source XMM register or a 128-bit memory location and writes the difference to bits [127:64] of the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VHSUBPD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Subtracts the packed double-precision values in bits [127:64] from the value in bits [63:0] of the first source XMM register and writes the difference to bits [63:0] of the destination XMM register; subtracts the corresponding values of the second source XMM register or a 128-bit memory location and writes the difference to bits [127:64] of the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Subtracts the packed double-precision values in bits [127:64] from the value in bits [63:0] of the of the first source YMM register and writes the difference to bits [63:0] of the destination YMM register; subtracts the corresponding values of the second source YMM register or a 256-bit memory location and writes the difference to bits [127:64] of the destination. Performs the same process for the upper 128 bits of the sources and destination.

HSUBPS VHSUBPS Horizontal Subtract Packed Single

Subtracts adjacent pairs of single-precision floating-point values in two source operands and writes the differences to a destination.

There are legacy and extended forms of the instruction:

HSUBPS

Subtracts the packed single-precision values in bits [63:32] from the values in bits [31:0] of the first source XMM register and writes the difference to bits [31:0] of the destination; subtracts the packed single-precision values in bits [127:96] from the value in bits [95:64] of the first source register and writes the difference to bits [63:32] of the destination. Subtracts the corresponding values of the second source XMM register or a 128-bit memory location and writes the differences to bits [95:64] and [127:96] of the destination. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VHSUBPS

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Subtracts the packed single-precision values in bits [63:32] from the value in bits [31:0] of the first source XMM register and writes the difference to bits [31:0] of the destination XMM register; subtracts the packed single-precision values in bits [127:96] from the value bits [95:64] of the first source register and writes the sum to bits [63:32] of the destination. Subtracts the corresponding values of the second source XMM register or a 128-bit memory location and writes the differences to bits [95:64] and [127:96] of the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Subtracts the packed single-precision values in bits [63:32] from the value in bits [31:0] of the first source YMM register and writes the difference to bits [31:0] of the destination YMM register; subtracts the packed single-precision values in bits [127:96] from the value in bits [95:64] of the first source register and writes the difference to bits [63:32] of the destination. Subtracts the corresponding values of the second source YMM register or a 256-bit memory location and writes the differences to bits [95:64] and [127:96] of the destination. Performs the same process for the upper 128 bits of the sources and destination.

[AMD Public Use]

INSERTPS Insert
VINSERTPS Packed Single-Precision Floating-Point

Copies a selected single-precision floating-point value from a source operand to a selected location in a destination register and optionally clears selected elements of the destination. The legacy and extended forms of the instruction treat the remaining elements of the destination in different ways.

Selections are specified by three fields of an immediate 8-bit operand:

7	6	5	4	3	2	1	0
COUNT_S		COUNT_D		ZMASK			

COUNT_S — The binary value of the field specifies a 32-bit element of a source register, counting upward from the low-order doubleword. COUNT_S is used only for register source; when the source is a memory operand, COUNT_S = 0.

COUNT_D — The binary value of the field specifies a 32-bit destination element, counting upward from the low-order doubleword.

ZMASK — Set a bit to clear a 32-bit element of the destination.

There are legacy and extended forms of the instruction:

INSERTPS

The source operand is an XMM register or a 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

When the source operand is a register, the instruction copies the 32-bit element of the source specified by Count_S to the location in the destination specified by Count_D, and clears destination elements as specified by ZMask. Elements of the destination that are not cleared are not affected.

When the source operand is a memory location, the instruction copies a 32-bit value from memory, to the location in the destination specified by Count_D, and clears destination elements as specified by ZMask. Elements of the destination that are not cleared are not affected.

VINSERTPS

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is an XMM register or a 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

When the second source operand is a register, the instruction copies the 32-bit element of the source specified by Count_S to the location in the destination specified by Count_D. The other elements of the destination are either copied from the first source operand or cleared as specified by ZMask.

When the second source operand is a memory location, the instruction copies a 32-bit value from the source to the location in the destination specified by Count_D. The other elements of the destination are either copied from the first source operand or cleared as specified by ZMask.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

[AMD Public Use]

INSERTQ Insert Field

Inserts bits from the lower 64 bits of the source operand into the lower 64 bits of the destination operand. No other bits in the lower 64 bits of the destination are modified. The upper 64 bits of the destination are undefined.

The least-significant *l* bits of the source operand are inserted into the destination, with the least-significant bit of the source operand inserted at bit position *n*, where *l* and *n* are defined as the *field length* and *bit index*, respectively.

Bits (*field length* – 1):0 of the source operand are inserted into bits (*bit index* + *field length* – 1):(*bit index*) of the destination. If the sum of the *bit index* + *length field* is greater than 64, the results are undefined.

For example, if the *bit index* is 32 (20h) and the field length is 16 (10h), then the result in the destination register will be *source operand*[15:0] in bits 47:32. Bits 63:48 and bits 31:0 are not modified.

A value of zero in the *field length* is defined as a length of 64. If the *length field* is 0 and the *bit index* is 0, bits 63:0 of the source operand are inserted. For any other value of the *bit index*, the results are undefined.

The bits to insert are located in the XMM2 source operand. The *bit index* and *field length* can be specified as immediate values or can be specified in the XMM source operand. In the immediate form, the *bit index* and the *field length* are specified by the fourth (second immediate byte) and third operands (first immediate byte), respectively. In the register form, the *bit index* and *field length* are specified in bits [77:72] and bits [69:64] of the source XMM register, respectively. The *bit index* and *field length* are each six bits in length; other bits in the field are ignored.

The diagram below illustrates the operation of this instruction.

None

MXCSR Flags Affected

None

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

KANDB AND Mask Register Byte

Performs a bitwise AND of the low byte value in the first source mask register with the corresponding value in the second source mask register and write the results to the low word of the destination register. Bits above the low byte are set to zero.

Instruction Support

Form	Subset
VEX KANDB	AVX512DQ

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Encoding			
	VEX	RXB.Map	W.vvvv.L.pp	Opcode
KANDB *k1, k2, k3*	C4	RXB.1	0.vvvv.1.01	41 /r

Related Instructions

KANDQ, KANDD, KANDW

rFLAGS Affected

None

MXCSR Flags Affected

None

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

KANDD — AND Mask Register Doubleword

Performs a logical AND of the low doubleword value in the first source mask register with the corresponding value in the second source mask register and write the results to the low doubleword of the destination register. Bits above the low doubleword are set to zero.

Instruction Support

Form	Subset
VEX KANDD	AVX512BW

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Encoding			
	VEX	RXB.Map	W.vvvv.L.pp	Opcode
KANDD *k1, k2, k3*	C4	RXB.1	1.vvvv.1.01	41 /r

[AMD Public Use]

LDDQU VLDDQU — Load Unaligned Double Quadword

Loads unaligned double quadwords from a memory location to a destination register.

Like the (V)MOVUPD instructions, (V)LDDQU loads a 128-bit or 256-bit operand from an unaligned memory location. However, to improve performance when the memory operand is actually misaligned, (V)LDDQU may read an aligned 16 or 32 bytes to get the first part of the operand, and an aligned 16 or 32 bytes to get the second part of the operand. This behavior is implementation-specific, and (V)LDDQU may only read the exact 16 or 32 bytes needed for the memory operand. If the memory operand is in a memory range where reading extra bytes can cause performance or functional issues, use (V)MOVUPD instead of (V)LDDQU.

Memory operands that are not aligned on 16-byte or 32-byte boundaries do not cause general-protection exceptions.

There are legacy and extended forms of the instruction:

LDDQU

The source operand is an unaligned 128-bit memory location. The destination operand is an XMM register. Bits above 127 of the corresponding YMM register are not affected.

VLDDQU

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is an unaligned 128-bit memory location. The destination operand is an XMM register. Bits above 127 of the YMM register that corresponds to the destination register are cleared.

YMM Encoding

The source operand is an unaligned 256-bit memory location. The destination operand is a YMM register.

Instruction Support

Form	Subset
LDDQU	SSE3
VEX VLDDQU	AVX

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

[AMD Public Use]

Instruction Encoding

			A	REX, F2, F3, or 66 prefix preceding VEX prefix.
	S	S	X	Lock prefix (F0h) preceding opcode.
Device not available, #NM	S	S	X	CR0.TS = 1.
Stack, #SS	S	S	X	Memory address exceeding stack segment limit or non-canonical.
General protection, #GP	S	S	X	Memory address exceeding data segment limit or non-canonical.
	S	S	X	Write to a read-only data segment.
			X	Null data segment used to reference memory.
Alignment check, #AC	S	S	X	Memory operand not 16-byte aligned when alignment checking enabled.
Page fault, #PF		S	X	Instruction execution caused a page fault.

X — AVX and SSE exception
A — AVX exception
S — SSE exception

[AMD Public Use]

LDMXCSR Load
VLDMXCSR MXCSR Control/Status Register

Loads the MXCSR register with a 32-bit value from memory.

For both legacy LDMXCSR and extended VLDMXCSR forms of the instruction, the source operand is a 32-bit memory location and the destination operand is the MXCSR.

If an MXCSR load clears a SIMD floating-point exception mask bit and sets the corresponding exception flag bit, a SIMD floating-point exception is not generated immediately. An exception is generated only when the next instruction that operates on an XMM or YMM register operand and causes that particular SIMD floating-point exception to be reported executes.

A general protection exception occurs if the instruction attempts to load non-zero values into reserved MXCSR bits. Software can use MXCSR_MASK to determine which bits are reserved. For details, see “128-Bit, 64-Bit, and x87 Programming” in Volume 2.

The MXCSR register is described in “Registers” in Volume 1.

Instruction Support

Form	Subset
LDMXCSR	SSE

[AMD Public Use]

MASKMOVDQU Masked Move
VMASKMOVDQU Double Quadword Unaligned

Moves bytes from the first source operand to a memory location specified by the DS:rDI register. Bytes are selected by mask bits in the second source operand. The memory location may be unaligned.

The mask consists of the most significant bit of each byte of the second source register. When a mask bit = 1, the corresponding byte of the first source register is written to the destination; when a mask bit = 0, the corresponding byte is not written.

Exception and trap behavior for elements not selected for storage to memory is implementation dependent. For instance, a given implementation may signal a data breakpoint or a page fault for bytes that are zero-masked and not actually written.

The instruction implicitly uses weakly-ordered, write-combining buffering for the data, as described in “Buffering and Combining Memory Writes” in Volume 2. For data that is shared by multiple processors, this instruction should be used together with a fence instruction in order to ensure data coherency (see “Cache and TLB Management” in Volume 2).

There are legacy and extended forms of the instruction:

MASKMOVDQU

The first source operand is an XMM register. The second source operand is an XMM register. The destination is a 128-bit memory location.

VMASKMOVDQU

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is an XMM register. The destination is a 128-bit memory location.

Instruction Support

Form	Subset
MASKMOVDQU	SSE2
VEX VMASKMOVDQU	AVX

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

[AMD Public Use]

MAXPD Maximum
VMAXPD Packed Double-Precision Floating-Point

Compares each packed double-precision floating-point value of the first source operand to the corresponding value of the second source operand and writes the numerically greater value into the corresponding location of the destination.

If both source operands are equal to zero, the value of the second source operand is returned. If either operand is a NaN (SNaN or QNaN), and invalid-operation exceptions are masked, the second source operand is written to the destination.

There are legacy and extended forms of the instruction:

MAXPD

Compares two pairs of packed double-precision floating-point values.

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source operand is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMAXPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Compares two pairs of packed double-precision floating-point values. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Compares four pairs of packed double-precision floating-point values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Compares eight pairs of packed double-precision floating-point values. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

MAXPS Maximum
VMAXPS Packed Single-Precision Floating-Point

Compares each packed single-precision floating-point value of the first source operand to the corresponding value of the second source operand and writes the numerically greater value into the corresponding location of the destination.

If both source operands are equal to zero, the value of the second source operand is returned. If either operand is a NaN (SNaN or QNaN), and invalid-operation exceptions are masked, the second source operand is written to the destination.

There are legacy and extended forms of the instruction:

MAXPS

Compares four pairs of packed single-precision floating-point values. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source operand is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMAXPS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Compares four pairs of packed single-precision floating-point values. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Compares eight pairs of packed single-precision floating-point values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Compares sixteen pairs of packed single-precision floating-point values. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

MAXSD Maximum
VMAXSD Scalar Double-Precision Floating-Point

Compares the scalar double-precision floating-point value in the low-order 64 bits of the first source operand to a corresponding value in the second source operand and writes the numerically greater value into the low-order 64 bits of the destination.

If both source operands are equal to zero, the value of the second source operand is returned. If either operand is a NaN (SNaN or QNaN), and invalid-operation exceptions are masked, the second source operand is written to the destination.

There are legacy and extended forms of the instruction:

MAXSD

The first source operand is an XMM register. The second source operand is an XMM register or a 64-bit memory location. The first source register is also the destination. When the second source is a 64-bit memory location, the upper 64 bits of the first source register are copied to the destination. Bits [127:64] of the destination are not affected. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMAXSD

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is an XMM register or a 64-bit memory location. The destination is an XMM register. When the second source is a 64-bit memory location, the upper 64 bits of the first source register are copied to the destination. Bits [127:64] of the destination are copied from bits [127:64] of the first source. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

SIMD floating-point, #XF	S	S	X	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.

[AMD Public Use]

Exceptions

Exception	Mode			Cause of Exception
	Real	Virt	Prot	
SIMD Floating-Point Exceptions				
Invalid operation, IE	S	S	X	A source operand was an SNaN value.
	S	S	X	Undefined operation.
Denormalized operand, DE	S	S	X	A source operand was a denormal value.
X — AVX and SSE exception *A — AVX exception* *S — SSE exception*				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

MINPD Minimum
VMINPD Packed Double-Precision Floating-Point

Compares each packed double-precision floating-point value of the first source operand to the corresponding value of the second source operand and writes the numerically lesser value into the corresponding location of the destination.

If both source operands are equal to zero, the value of the second source operand is returned. If either operand is a NaN (SNaN or QNaN), and invalid-operation exceptions are masked, the second source operand is written to the destination.

There are legacy and extended forms of the instruction:

MINPD

Compares two pairs of packed double-precision floating-point values.

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source operand is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMINPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Compares two pairs of packed double-precision floating-point values. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Compares four pairs of packed double-precision floating-point values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Compares eight pairs of packed double-precision floating-point values. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

MOVAPD VMOVAPD Move Aligned Packed Double-Precision Floating-Point

Moves packed double-precision floating-point values. Values can be moved from a register or memory location to a register; or from a register to a register or memory location.

A memory operand that is not aligned causes a general-protection exception.

There are legacy and extended forms of the instruction:

MOVAPD

Moves two double-precision floating-point values. There are encodings for each type of move. The source operand is an XMM register or a 128-bit memory location. The destination operand is an XMM register. The source operand is an XMM register. The destination operand is an XMM register or a 128-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VMOVAPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Moves two double-precision floating-point values. There are encodings for each type of move. The source operand is an XMM register or a 128-bit memory location. The destination operand is an XMM register. The source operand is an XMM register. The destination operand is an XMM register or a 128-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Moves four double-precision floating-point values. There are encodings for each type of move. The source operand is a YMM register or a 256-bit memory location. The destination operand is a YMM register. The source operand is a YMM register. The destination operand is a YMM register or a 256-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Moves eight double-precision floating-point values. There are encodings for each type of move. The source operand is a ZMM register or a 512-bit memory location. The destination operand is a ZMM register. The source operand is a ZMM register. The destination operand is a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

[AMD Public Use]

MOVAPS VMOVAPS Move Aligned Packed Single-Precision Floating-Point

Moves packed single-precision floating-point values. Values can be moved from a register or memory location to a register; or from a register to a register or memory location.

A memory operand that is not aligned causes a general-protection exception.

There are legacy and extended forms of the instruction:

MOVAPS

Moves four single-precision floating-point values.

There are encodings for each type of move.

- The source operand is an XMM register or a 128-bit memory location. The destination operand is an XMM register.
- The source operand is an XMM register. The destination operand is an XMM register or a 128-bit memory location.

Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VMOVAPS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Moves four single-precision floating-point values. There are encodings for each type of move. The source operand is an XMM register or a 128-bit memory location. The destination operand is an XMM register. The source operand is an XMM register. The destination operand is an XMM register or a 128-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Moves eight single-precision floating-point values. There are encodings for each type of move. The source operand is a YMM register or a 256-bit memory location. The destination operand is a YMM register. The source operand is a YMM register. The destination operand is a YMM register or a 256-bit memory location.

ZMM Encoding

Moves sixteen single-precision floating-point values. There are encodings for each type of move. The source operand is a ZMM register or a 512-bit memory location. The destination operand is a ZMM register. The source operand is a ZMM register. The destination operand is a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

MOVD Move Doubleword
VMOVD

Moves 32-bit values. A value can be moved from a general-purpose register or memory location to the low-order bits of an XMM register, with zero-extension to 128 bits; or from the low-order bits of an XMM register to a general-purpose register or memory location.

Note that some developer tools use different mnemonics for the (V)MOVD and (V)MOVQ instructions.

There are legacy and extended forms of the instruction:

MOVD

There are two legacy encodings:

- The source operand is a 32-bit general-purpose register or a 32-bit memory location. The destination is an XMM register. The 32-bit value is zero-extended to 128 bits. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.
- The source operand is an XMM register. The destination is a 32-bit general-purpose register or a 32-bit memory location.

VMOVD

The extended form of the instruction has several 128-bit encodings:

- The source operand is a 32-bit general-purpose register or a 32-bit memory location. The destination is an XMM register. The 32-bit value is zero-extended to 128 bits. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.
- The source operand is an XMM register. The destination is a 32-bit general-purpose register or a 32-bit memory location.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Instruction Support

Form	Subset
MOVD	SSE2
VEX VMOVD	AVX
EVEX VMOVD	AVX512F

[AMD Public Use]

MOVDDUP Move and Duplicate
VMOVDDUP Double-Precision Floating-Point

Moves and duplicates double-precision floating-point values.

There are legacy and extended forms of the instruction:

MOVDDUP

Moves and duplicates one quadword value.

The source operand is either the low 64 bits of an XMM register or the address of the least-significant byte of 64 bits of data in memory. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMOVDDUP

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Moves and duplicates one quadword value. The source operand is either the low 64 bits of an XMM register or the address of the least-significant byte of 64 bits of data in memory. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves and duplicates two even-indexed quadword values. The source operand is a YMM register or the address of the least-significant byte of 256 bits of data in memory. The destination is a YMM register. Bits [63:0] of the source are written to bits [127:64] and [63:0] of the destination; bits [191:128] of the source are written to bits [255:192] and [191:128] of the destination. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Moves and duplicates four even-indexed quadword values. The source operand is a ZMM register or the address of the least-significant byte of 512 bits of data in memory. The destination is a ZMM register.

Bits [63:0] of the source are written to bits [127:64] and [63:0] of the destination; bits [191:128] of the source are written to bits [255:192] and [191:128] of the destination; bits [319:256] of the source are written to bits [383:320] and [319:256] of the destination; bits [191:384] of the source are written to bits [511:448] and [447:384] of the destination.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

MOVDQA
VMOVDQA
VMOVDQA32
VMOVDQA64

Move Aligned Double Quadword

Moves aligned packed integer values. Values can be moved from a register or a memory location to a register, or from a register to a register or a memory location.

A memory operand that is not aligned causes a general-protection exception.

There are legacy and extended forms of the instruction:

MOVDQA

Moves two aligned quadwords (128-bit move). There are two encodings.

- The source operand is an XMM register. The destination is an XMM register or a 128-bit memory location.
- The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMOVDQA

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Moves two aligned quadwords (128-bit move). There are two encodings.

- The source operand is an XMM register. The destination is an XMM register or a 128-bit memory location.
- The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves four aligned quadwords (256-bit move). There are two encodings.

- The source operand is a YMM register. The destination is a YMM register or a 256-bit memory location.
- The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register.

The EVEX encoded versions of the VMOVDQA32 instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

The EVEX encoded versions of the VMOVDQA64 instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Move Unaligned Double Quadword

Moves unaligned packed integer values. Values can be moved from a register or a memory location to a register, or from a register to a register or a memory location.

There are legacy and extended forms of the instruction:

MOVDQU

Moves two unaligned quadwords (128-bit move). There are two encodings.

- The source operand is an XMM register. The destination is an XMM register or a 128-bit memory location.
- The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMOVDQU

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Moves two unaligned quadwords (128-bit move). There are two encodings.

- The source operand is an XMM register. The destination is an XMM register or a 128-bit memory location.
- The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves four unaligned quadwords (256-bit move). There are two encodings.

- The source operand is a YMM register. The destination is a YMM register or a 256-bit memory location.
- The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register.

The EVEX encoded versions of the VMOVDQU8 instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

The EVEX encoded versions of the VMOVDQU16 instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

The EVEX encoded versions of the VMOVDQU32 instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

The EVEX encoded versions of the VMOVDQU64 instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

MOVHLPS Move High to Low
VMOVHLPS Packed Single-Precision Floating-Point

Moves two packed single-precision floating-point values from the high quadword of an XMM register to the low quadword of an XMM register.

There are legacy and extended forms of the instruction:

MOVHLPS

The source operand is bits [127:64] of an XMM register. The destination is bits [63:0] of an XMM register. Bits [127:64] of the destination are not affected. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VMOVHLPS

The extended form of the instruction has only 128-bit encoding:

The source operands are bits [127:64] of two XMM registers. The destination is a third XMM register. Bits [127:64] of the first source are moved to bits [127:64] of the destination; bits [127:64] of the second source are moved to bits [63:0] of the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

MOVHPD VMOVHPD — Move High Packed Double-Precision Floating-Point

Moves a packed double-precision floating-point value. Values can be moved from a 64-bit memory location to the high-order quadword of an XMM register, or from the high-order quadword of an XMM register to a 64-bit memory location.

There are legacy and extended forms of the instruction:

MOVHPD

There are two encodings.

- The source operand is a 64-bit memory location. The destination is bits [127:64] of an XMM register.
- The source operand is bits [127:64] of an XMM register. The destination is a 64-bit memory location.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMOVHPD

The extended form of the instruction has two 128-bit, 256-bit, and 512-bit encodings:

- There are two source operands. The first source is an XMM register. The second source is a 64-bit memory location. The destination is an XMM register. Bits [63:0] of the source register are written to bits [63:0] of the destination; bits [63:0] of the source memory location are written to bits [127:64] of the destination.
- The source operand is bits [127:64] of an XMM register. The destination is a 64-bit memory location.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

MOVLPD Move Low
VMOVLPD Packed Double-Precision Floating-Point

Moves a packed double-precision floating-point value. Values can be moved from a 64-bit memory location to the low-order quadword of an XMM register, or from the low-order quadword of an XMM register to a 64-bit memory location.

There are legacy and extended forms of the instruction:

MOVLPD

There are two encodings.

- The source operand is a 64-bit memory location. The destination is bits [63:0] of an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.
- The source operand is bits [63:0] of an XMM register. The destination is a 64-bit memory location.

VMOVLPD

The extended form of the instruction has two 128-bit encodings.

- There are two source operands. The first source is an XMM register. The second source is a 64-bit memory location. The destination is an XMM register. Bits [127:64] of the source register are written to bits [127:64] of the destination; bits [63:0] of the source memory location are written to bits [63:0] of the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.
- The source operand is bits [63:0] of an XMM register. The destination is a 64-bit memory location.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

MOVMSKPD Extract Sign Mask
VMOVMSKPD Packed Double-Precision Floating-Point

Extracts the sign bits of packed double-precision floating-point values from an XMM register, zero-extends the value, and writes it to the low-order bits of a general-purpose register.

There are legacy and extended forms of the instruction:

MOVMSKPD

Extracts two mask bits.

The source operand is an XMM register. The destination can be either a 64-bit or a 32-bit general purpose register. Writes the extracted bits to positions [1:0] of the destination and clears the remaining bits. Bits above 127 of the YMM register that corresponds to the source are not affected.

VMOVMSKPD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Extracts two mask bits.

The source operand is an XMM register. The destination can be either a 64-bit or a 32-bit general purpose register. Writes the extracted bits to positions [1:0] of the destination and clears the remaining bits.

YMM Encoding

Extracts four mask bits.

The source operand is a YMM register. The destination can be either a 64-bit or a 32-bit general purpose register. Writes the extracted bits to positions [3:0] of the destination and clears the remaining bits.

MOVMSKPS VMOVMSKPS — Extract Sign Mask Packed Single-Precision Floating-Point

Extracts the sign bits of packed single-precision floating-point values from an XMM register, zero-extends the value, and writes it to the low-order bits of a general-purpose register.

There are legacy and extended forms of the instruction:

MOVMSKPS

Extracts four mask bits.

The source operand is an XMM register. The destination can be either a 64-bit or a 32-bit general purpose register. Writes the extracted bits to positions [3:0] of the destination and clears the remaining bits.

VMOVMSKPS

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Extracts four mask bits.

The source operand is an XMM register. The destination can be either a 64-bit or a 32-bit general purpose register. Writes the extracted bits to positions [3:0] of the destination and clears the remaining bits.

YMM Encoding

Extracts eight mask bits.

The source operand is a YMM register. The destination can be either a 64-bit or a 32-bit general purpose register. Writes the extracted bits to positions [7:0] of the destination and clears the remaining bits.

Instruction Support

MOVNTDQ VMOVNTDQ — Move Non-Temporal Double Quadword

Moves double quadword values from a register to a memory location.

Indicates to the processor that the data is non-temporal, and is unlikely to be used again soon. The processor treats the store as a write-combining (WC) memory write, which minimizes cache pollution. The method of minimization depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” in Volume 1.

The instruction is weakly-ordered with respect to other instructions that operate on memory. Software should use an SFENCE or MFENCE instruction to force strong memory ordering of MOVNTDQ with respect to other stores.

An attempted store to a non-aligned memory location results in a #GP exception.

There are legacy and extended forms of the instruction:

MOVNTDQ

Moves one 128-bit value. The source operand is an XMM register. The destination is a 128-bit memory location.

VMOVNTDQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Moves one 128-bit value. The source operand is an XMM register. The destination is a 128-bit memory location.

YMM Encoding

Moves two 128-bit values. The source operand is a YMM register. The destination is a 256-bit memory location.

ZMM Encoding

Moves four 128-bit values. The source operand is a ZMM register. The destination is a 512-bit memory location.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

MOVNTDQA VMOVNTDQA — Move Non-Temporal Double Quadword Aligned

Loads an XMM/YMM register from a naturally-aligned 128-bit or 256-bit memory location.

Indicates to the processor that the data is non-temporal, and is unlikely to be used again soon. The processor treats the load as a write-combining (WC) memory read, which minimizes cache pollution. The method of minimization depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” in Volume 1.

The instruction is weakly-ordered with respect to other instructions that operate on memory. Software should use an MFENCE instruction to force strong memory ordering of MOVNTDQA with respect to other reads.

An attempted load from a non-aligned memory location results in a #GP exception.

There are legacy and extended forms of the instruction:

MOVNTDQA

Loads a 128-bit value into the specified XMM register from a 16-byte aligned memory location.

VMOVNTDQA

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Loads a 128-bit value into the specified XMM register from a 16-byte aligned memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Loads a 256-bit value into the specified YMM register from a 32-byte aligned memory location. Bits above bit 255of the ZMM/YMM register that corresponds to the destination are cleared.

ZMM Encoding

Loads a 512-bit value in the specified ZMM register from a 64-byte aligned memory location.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

MOVNTPD VMOVNTPD Move Non-Temporal Packed Double-Precision Floating-Point

Moves packed double-precision floating-point values from a register to a memory location.

Indicates to the processor that the data is non-temporal, and is unlikely to be used again soon. The processor treats the store as a write-combining (WC) memory write, which minimizes cache pollution. The method of minimization depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” in Volume 1.

The instruction is weakly-ordered with respect to other instructions that operate on memory. Software should use an SFENCE or MFENCE instruction to force strong memory ordering of MOVNTDQ with respect to other stores.

An attempted store to a non-aligned memory location results in a #GP exception.

There are legacy and extended forms of the instruction:

MOVNTPD

Moves two values. The source operand is an XMM register. The destination is a 128-bit memory location.

VMOVNTPD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Moves two values. The source operand is an XMM register. The destination is a 128-bit memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves four values. The source operand is a YMM register. The destination is a 256-bit memory location. Bits above bit 255 of the ZMM/YMM register that corresponds to the destination are cleared.

ZMM Encoding

Moves eight values. The source operand is a ZMM register. The destination is a 512-bit memory location.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

MOVNTPS VMOVNTPS — Move Non-Temporal Packed Single-Precision Floating-Point

Moves packed single-precision floating-point values from a register to a memory location.

Indicates to the processor that the data is non-temporal, and is unlikely to be used again soon. The processor treats the store as a write-combining (WC) memory write, which minimizes cache pollution. The method of minimization depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” in Volume 1.

The instruction is weakly-ordered with respect to other instructions that operate on memory. Software should use an SFENCE or MFENCE instruction to force strong memory ordering of MOVNTDQ with respect to other stores.

An attempted store to a non-aligned memory location results in a #GP exception.

There are legacy and extended forms of the instruction:

MOVNTPS

Moves four values. The source operand is an XMM register. The destination is a 128-bit memory location.

VMOVNTPS

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Moves four values. The source operand is an XMM register. The destination is a 128-bit memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves eight values. The source operand is a YMM register. The destination is a 256-bit memory location. Bits above bit 255 of the ZMM/YMM register that corresponds to the destination are cleared.

ZMM Encoding

Moves sixteen values. The source operand is a ZMM register. The destination is a 512-bit memory location.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

MOVQ VMOVQ Move Quadword

Moves 64-bit values. A value can be moved from the low 64 bits of an XMM register, a general-purpose register or memory location to the low-order bits of an XMM register, with zero-extension to 128 bits; or from the low-order bits of an XMM register to the low-order bits of an XMM register, a general-purpose register or memory location.

Note that some developer tools use different mnemonics for the (V)MOVD and (V)MOVQ instructions.

There are legacy and extended forms of the instruction:

MOVQ

There are several legacy encodings:

- The source operand is an XMM register, a 64-bit general-purpose register or a 64-bit memory location. The destination is an XMM register. The 64-bit value is zero-extended to 128 bits. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.
- The source operand is an XMM register. The destination is an XMM register, a 64-bit general-purpose register or a 64-bit memory location.

VMOVQ

The extended form of the instruction has several 128-bit encodings:

- The source operand is an XMM register, a 64-bit general-purpose register or a 64-bit memory location. The destination is an XMM register. The 64-bit value is zero-extended to 128 bits. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.
- The source operand is an XMM register. The destination is an XMM register, a 64-bit general-purpose register or a 64-bit memory location. If the destination is an XMM register, the 64-bit value is zero-extended to 128 bits and bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Instruction Support

Form	Subset
MOVQ	SSE2
VEX VMOVQ	AVX
EVEX VMOVQ	AVX512F

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

MOVSD Move
VMOVSD Scalar Double-Precision Floating-Point

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Moves scalar double-precision floating point values. The source is a low-order quadword of an XMM register or a 64-bit memory location. The destination is a low-order quadword of an XMM register or a 64-bit memory location.

There are legacy and extended forms of the instruction:

MOVSD

There are two encodings.

- The source operand is an XMM register or a 64-bit memory location. The destination is an XMM register. If the source operand is a register, bits [127:64] of the destination are not affected. If the source operand is a 64-bit memory location, the upper 64 bits of the destination are cleared.
- The source operand is an XMM register. The destination is an XMM register or a 64-bit memory location. When the destination is a register, bits [127:64] of the destination are not affected.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMOVSD

The extended form of the instruction has four 128-bit encodings. Two of the encodings are functionally equivalent.

- The source operand is a 64-bit memory location. The destination is an XMM register. The 64-bit value is zero-extended to 128 bits.
- The source operand is an XMM register. The destination is a 64-bit memory location.
- Two functionally-equivalent encodings. There are two source XMM registers. The destination is an XMM register. Bits [127:64] of the first source register are copied to bits [127:64] of the destination; the 64-bit value in bits [63:0] of the second source register is written to bits [63:0] of the destination.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

This instruction must not be confused with the MOVSD (move string doubleword) instruction of the general-purpose instruction set. Assemblers can distinguish the instructions by the number and type of operands.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

Instruction Support

Form	Subset
MOVSD	SSE2
VEX VMOVSD	AVX
EVEX VMOVSD	AVX512F

MOVSHDUP VMOVSHDUP — Move High and Duplicate Single-Precision

Moves and duplicates odd-indexed single-precision floating-point values.

There are legacy and extended forms of the instruction:

MOVSHDUP

Moves and duplicates two odd-indexed single-precision floating-point values.

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [127:96] of the source are duplicated and written to bits [127:96] and [95:64] of the destination. Bits [63:32] of the source are duplicated and written to bits [63:32] and [31:0] of the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMOVSHDUP

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Moves and duplicates two odd-indexed single-precision floating-point values. The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [127:96] of the source are duplicated and written to bits [127:96] and [95:64] of the destination. Bits [63:32] of the source are duplicated and written to bits [63:32] and [31:0] of the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves and duplicates four odd-indexed single-precision floating-point values. The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. Bits [255:224] of the source are duplicated and written to bits [255:224] and [223:192] of the destination. Bits [191:160] of the source are duplicated and written to bits [191:160] and [159:128] of the destination. Bits [127:96] of the source are duplicated and written to bits [127:96] and [95:64] of the destination. Bits [63:32] of the source are duplicated and written to bits [63:32] and [31:0] of the destination.

ZMM Encoding

Moves and duplicates eight odd-indexed single-precision floating-point values. The source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register. Bits [511:480] of the source are duplicated and written to bits [511:480] and [479:448] of the destination. Bits [447:416] of the source are duplicated and written to bits [447:416] and [415:384] of the destination. Bits [383:352] of the source are duplicated and written to bits [383:352] and [351:320] of the destination.Bits [319:288] of the source are duplicated and written to bits [319:288] and [287:256] of the destination. Bits [255:224] of the source are duplicated and written to bits [255:224] and [223:192] of the destination. Bits [191:160] of the source are duplicated and written to bits [191:160] and [159:128] of the destination.Bits [127:96] of the source are duplicated and written to bits [127:96] and [95:64] of the destination. Bits [63:32] of the source are duplicated and written to bits [63:32] and [31:0] of the destination.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

MOVSLDUP VMOVSLDUP — Move Low and Duplicate Single-Precision

Moves and duplicates even-indexed single-precision floating-point values.

There are legacy and extended forms of the instruction:

MOVSLDUP

Moves and duplicates two even-indexed single-precision floating-point values.

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [95:64] of the source are duplicated and written to bits [127:96] and [95:64] of the destination. Bits [31:0] of the source are duplicated and written to bits [63:32] and [31:0] of the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMOVSLDUP

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Moves and duplicates two even-indexed single-precision floating-point values. The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [95:64] of the source are duplicated and written to bits [127:96] and [95:64] of the destination. Bits [31:0] of the source are duplicated and written to bits [63:32] and [31:0] of the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves and duplicates four even-indexed single-precision floating-point values. The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. Bits [223:192] of the source are duplicated and written to bits [255:224] and [223:192] of the destination. Bits [159:128] of the source are duplicated and written to bits [191:160] and [159:128] of the destination. Bits [95:64] of the source are duplicated and written to bits [127:96] and [95:64] of the destination. Bits [31:0] of the source are duplicated and written to bits [63:32] and [31:0] of the destination.

ZMM Encoding

Moves and duplicates eight even-indexed single-precision floating-point values. The source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register. Bits [479:448] of the source are duplicated and written to bits [511:480] and [479:448] of the destination. Bits [425:384] of the source are duplicated and written to bits [447:416] and [415:384] of the destination. Bits [351:320] of the source are duplicated and written to bits [383:352] and [351:320] of the destination. Bits [287:256] of the source are duplicated and written to bits [319:288] and [287:256] of the destination. Bits [223:192] of the source are duplicated and written to bits [255:224] and [223:192] of the destination. Bits [159:128] of the source are duplicated and written to bits [191:160] and [159:128] of the destination. Bits [96:64] of the source are duplicated and written to bits [127:96] and [95:64] of the destination. Bits [31:0] of the source are duplicated and written to bits [63:32] and [31:0] of the destination.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

[AMD Public Use]

MOVSS Move
VMOVSS Scalar Single-Precision Floating-Point

Moves scalar single-precision floating point values. The source is a low-order doubleword of an XMM register or a 32-bit memory location. The destination is a low-order doubleword of an XMM register or a 32-bit memory location.

There are legacy and extended forms of the instruction:

MOVSS

There are three encodings.

- The source operand is an XMM register. The destination is an XMM register. Bits [127:32] of the destination are not affected.
- The source operand is a 32-bit memory location. The destination is an XMM register. The 32-bit value is zero-extended to 128 bits.
- The source operand is an XMM register. The destination is an XMM register or a 32-bit memory location. When the destination is a register, bits [127:32] of the destination are not affected.

Bits above 127 of the YMM register that corresponds to the source are not affected.

VMOVSS

The extended form of the instruction has four 128-bit encodings. Two of the encodings are functionally equivalent.

- The source operand is a 32-bit memory location. The destination is an XMM register. The 32-bit value is zero-extended to 128 bits.
- The source operand is an XMM register. The destination is a 32-bit memory location.
- Two functionally equivalent encodings. There are two source XMM registers. The destination is an XMM register. Bits [127:32] of the first source register are copied to bits [127:32] of the destination; the 32-bit value in bits [31:0] of the second source register is written to bits [31:0] of the destination.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Instruction Support

Form	Subset
MOVSS	SSE
VEX VMOVSS	AVX
EVEX VMOVSS	AVX512F

MOVUPD VMOVUPD — Move Unaligned Packed Double-Precision Floating-Point

Moves packed double-precision floating-point values. Values can be moved from a register or memory location to a register; or from a register to a register or memory location.

A memory operand that is not aligned does not cause a general-protection exception.

There are legacy and extended forms of the instruction:

MOVUPD

Moves two double-precision floating-point values. There are encodings for each type of move.

- The source operand is an XMM register or a 128-bit memory location. The destination operand is an XMM register.
- The source operand is an XMM register. The destination operand is an XMM register or a 128-bit memory location.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMOVUPD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Moves two double-precision floating-point values. There are encodings for each type of move. The source operand is an XMM register or a 128-bit memory location. The destination operand is an XMM register. The source operand is an XMM register. The destination operand is an XMM register or a 128-bit memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves four double-precision floating-point values. There are encodings for each type of move. The source operand is a YMM register or a 256-bit memory location. The destination operand is a YMM register. The source operand is a YMM register. The destination operand is a YMM register or a 256-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Moves eight double-precision floating-point values. There are encodings for each type of move. The source operand is a ZMM register or a 512-bit memory location. The destination operand is a ZMM register. The source operand is a ZMM register. The destination operand is a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

MOVUPS Move Unaligned
VMOVUPS Packed Single-Precision Floating-Point

Moves packed single-precision floating-point values. Values can be moved from a register or memory location to a register; or from a register to a register or memory location.

A memory operand that is not aligned does not cause a general-protection exception.

There are legacy and extended forms of the instruction:

MOVUPS

Moves four single-precision floating-point values. There are encodings for each type of move. The source operand is an XMM register or a 128-bit memory location. The destination operand is an XMM register. The source operand is an XMM register. The destination operand is an XMM register or a 128-bit memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMOVUPS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Moves four single-precision floating-point values. There are encodings for each type of move. The source operand is an XMM register or a 128-bit memory location. The destination operand is an XMM register. The source operand is an XMM register. The destination operand is an XMM register or a 128-bit memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves eight single-precision floating-point values. There are encodings for each type of move. The source operand is a YMM register or a 256-bit memory location. The destination operand is a YMM register. The source operand is a YMM register. The destination operand is a YMM register or a 256-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Moves sixteen single-precision floating-point values. There are encodings for each type of move. The source operand is a ZMM register or a 512-bit memory location. The destination operand is a ZMM register. The source operand is a ZMM register. The destination operand is a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

MPSADBW VMPSADBW Multiple Sum of Absolute Differences

Calculates eight or sixteen sums of absolute differences of sequentially selected groups of four contiguous unsigned byte integers in the first source operand and a selected group of four contiguous unsigned byte integers in a second source operand and writes the eight or sixteen 16-bit unsigned integer sums to sequential words of the destination register. The 256-bit form of the instruction additionally performs a similar but independent calculation using the upper 128 bits of the source operands.

Figure 2-2 on page 353 provides a graphical representation of the operation of the instruction. The following description accompanies it.

The computation uses as inputs 11 bytes from the first source operand and 4 bytes in the second source operand. Bit fields in the imm8 operand specify the index of the right-most byte of each group.

Bits [1:0] of the immediate operand determine the index of the right-most byte of four contiguous bytes within the second source operand used in the operation that produces the result (or, in the case of the 256-bit form of the instruction, the lower 128 bits of the result). Bit 2 of the immediate operand determines the right-most index of the 11contiguous bytes in the first source operand used in the same calculation. In the 128-bit form of the instruction, bits [7:3] of the immediate operand are ignored.

Bits [4:3] of the immediate operand determine the index of the right-most byte of four contiguous bytes within the second source operand used in the operation that produces the upper 128 bits of the result in the 256-bit form of the instruction. Bit 5 of the immediate operand determines the right-most index of the 11 contiguous bytes within in the upper half of the first 256-bit source operand used in the same calculation. In the 256-bit form of the instruction, bits [7:6] of the immediate operand are ignored.

Each word of the destination register receives the result of a separate computation of the sum of absolute differences function applied to a specific pair of four-element vectors derived from the source operands. The sum of absolute differences function SumAbsDiff (A, B) takes as input two 4-element unsigned 8-bit integer vectors and produces a single unsigned 16-bit integer result. The function is defined as:

SumAbsDiff(A, B) = | A[0]-B[0] | + | A[1]-B[1] | + | A[2]-B[2] | + | A[3]-B[3] |

The sum of absolute differences function produces a quantitative measure of the difference between two 4-element vectors. Each of the calculations that generates a result uses this metric to assess the difference between the selected 4-byte vector from operand 2 (B in the above equation) with each of eight overlapping 4-byte vectors (A in the equation) selected sequentially from the first source operand.

The right-most word (Word 0) of the destination receives the result of the comparison of the right-most 4 bytes of the selected group of 11 from operand 1 (src1[i1+3 : i1], as shown in the figure) to the selected 4 bytes from operand 2 (src2[j1+3:j1], in the figure). Word 1 of the destination receives the result of the comparison of the four bytes starting at an offset of 1 from the right-most byte of the group of 11 (src1[i1+4 : i1+1] in the figure) to the 4 bytes from operand 2. Word 2 of the destination receives the result of the comparison of the four bytes starting at an offset of 2 from the right-most byte of the group of 11 (src1[i1+5 : i1+2], in the figure) to the selected 4 bytes from operand 2. This continues in like manner until the left-most four bytes of the 11 are compared to the 4 bytes from operand 2 with the result being written to Word 7. This completes the generation of the lower 128 bits of the result.

[AMD Public Use]

The generation of the upper 128 bits of the result for the 256-bit form of the instruction is performed in like manner using separately selected groups of bytes from the upper half of the 256-bit operands, as described above.

The following is a more formal description of the operation of the (V)MPSADBW instruction:

For both the 128-bit and 256-bit form of the instruction, the following set of operations is performed:

```
src1 and src2 are byte vectors that overlay the first and second source operand respectively.
dest is a word vector that overlays the destination register.
tmp1[ ] is an array of 4-element vectors derived from the first source operand.
tmp2 and tmp3 are 4-element vectors derived from the second source operand.

i1 = imm8[2] * 4
j1= imm8[1:0] * 4

tmp1[0] = {src1[i1+3], src1[i1+2], src1[i1+1], src1[i1]}
tmp1[1] = {src1[i1+4], src1[i1+3], src1[i1+2], src1[i1+1]}
tmp1[2] = {src1[i1+5], src1[i1+4], src1[i1+3], src1[i1+2]}
tmp1[3] = {src1[i1+6], src1[i1+5], src1[i1+4], src1[i1+3]}
tmp1[4] = {src1[i1+7], src1[i1+6], src1[i1+5], src1[i1+4]}
tmp1[5] = {src1[i1+8], src1[i1+7], src1[i1+6], src1[i1+5]}
tmp1[6] = {src1[i1+9], src1[i1+8], src1[i1+7], src1[i1+6]}
tmp1[7] = {src1[i1+10], src1[i1+9], src1[i1+8], src1[i1+7]}
tmp2 = {src2[j1+3], src2[j1+2], src2[j1+1], src2[j1]}

dest[0] = SumAbsDiff(tmp1[0], tmp2)
dest[1] = SumAbsDiff(tmp1[1], tmp2)
dest[2] = SumAbsDiff(tmp1[2], tmp2)
dest[3] = SumAbsDiff(tmp1[3], tmp2)
dest[4] = SumAbsDiff(tmp1[4], tmp2)
dest[5] = SumAbsDiff(tmp1[5], tmp2)
dest[6] = SumAbsDiff(tmp1[6], tmp2)
dest[7] = SumAbsDiff(tmp1[7], tmp2)
```

Additionally, for the 256-bit form of the instruction, the following set of operations is performed:

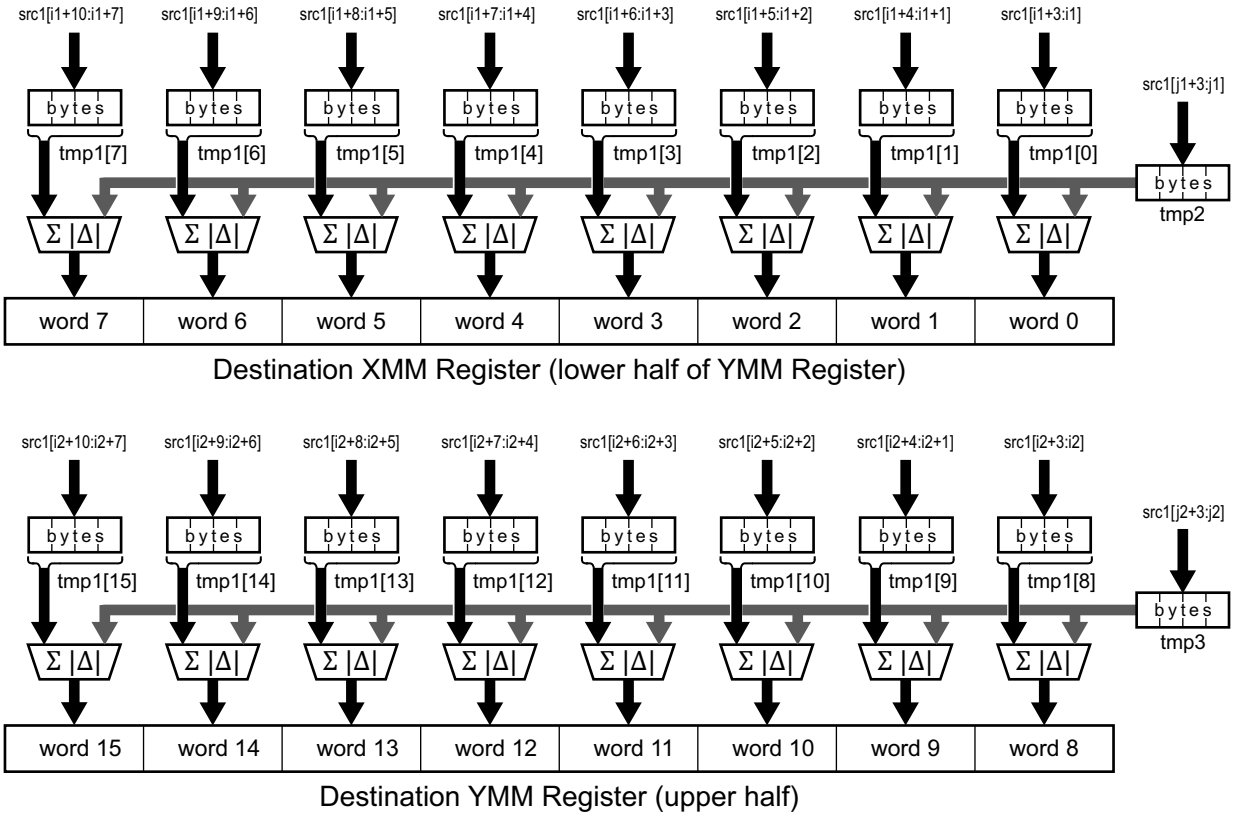
```
i2 = imm8[5] * 4 + 16
j2= imm8[4:3] * 4 +16

tmp1[8] = {src1[i2+3], src1[i2+2], src1[i2+1], src1[i2]}
tmp1[9] = {src1[i2+4], src1[i2+3], src1[i2+2], src1[i2+1]}
tmp1[10] = {src1[i2+5], src1[i2+4], src1[i2+3], src1[i2+2]}
tmp1[11] = {src1[i2+6], src1[i2+5], src1[i2+4], src1[i2+3]}
tmp1[12] = {src1[i2+7], src1[i2+6], src1[i2+5], src1[i2+4]}
tmp1[13] = {src1[i2+8], src1[i2+7], src1[i2+6], src1[i2+5]}
tmp1[14] = {src1[i2+9], src1[i2+8], src1[i2+7], src1[i2+6]}
tmp1[15] = {src1[i2+10], src1[i2+9], src1[i2+8], src1[i2+7]}
tmp3 = {src2[j2+3], src2[j2+2], src2[j2+1], src2[j2]}

dest[8] = SumAbsDiff(tmp1[8], tmp3)
dest[9] = SumAbsDiff(tmp1[9], tmp3)
dest[10] = SumAbsDiff(tmp1[10], tmp3)
dest[11] = SumAbsDiff(tmp1[11], tmp3)
dest[12] = SumAbsDiff(tmp1[12], tmp3)
dest[13] = SumAbsDiff(tmp1[13], tmp3)
```

[AMD Public Use]

dest[14] = SumAbsDiff(tmp1[14], tmp3)
dest[15] = SumAbsDiff(tmp1[15], tmp3)



Notes:
- i1 is a byte offset into source operand 1 (i1 = imm8[2] * 4).
- j1 is a byte offset into source operand 2 (j1 = imm8[1:0] * 4)
- i2 is a second byte offset into source operand 1 (i2 = imm8[5] * 4 + 16)
- j2 is a second byte offset into source operand 2 (j2 = imm8[4:3] * 4 + 16)
- Σ |Δ| represents the sum of absolute differences function which operates on two 4-element unsigned packed byte values and produces an unsigned 16-bit integer.

MPSADBW_instruct2.eps

Figure 2-2. (V)MPSADBW Instruction

There are legacy and extended forms of the instruction:

MPSADBW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VMPSADBW

The extended form of the instruction has 128-bit and 256-bit encodings.

[AMD Public Use]

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits [127:0] of the destination receive the results of the first 8 sums of absolute differences calculation using the selected bytes of the lower halves of the two source operands. Bits [255:128] of the destination receive the results of the second 8 sums of absolute differences calculation using selected bytes of the upper halves of the two source operands. Bits above bit 255 of the ZMM register that correspond to the destination are cleared.

Instruction Support

[AMD Public Use]

MULPD VMULPD Multiply Packed Double-Precision Floating-Point

Multiplies 2, 4, or 8 packed double-precision floating-point values of the first source operand by the corresponding packed double-precision floating-point value of the second source operand and writes the product of each multiplication into the corresponding element of the destination.

There are legacy and extended forms of the instruction:

MULPD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VMULPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

MULPS VMULPS Multiply Packed Single-Precision Floating-Point

Multiplies four, eight, or sixteen packed single-precision floating-point values of the first source operand by the corresponding packed single-precision floating-point value of the second source operand and writes the product of each multiplication into the corresponding elements of the destination.

There are legacy and extended forms of the instruction:

MULPS

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the desti-nation. Bits above bit 127 of the YMM/ZMM register corresponding to the destina-tion are not affected.

VMULPS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

MULSD VMULSD Multiply Scalar Double-Precision Floating-Point

Multiplies the double-precision floating-point value in the low-order quadword of the first source operand by the corresponding value in the low-order quadword of the second source operand and writes the result into the low-order quadword of the destination.

There are legacy and extended forms of the instruction:

MULSD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VMULSD

The extended forms of the instruction have 128-bit encodings only.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [127:64] of the first source operand are copied to bits [127:64] of the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Instruction Support

Form	Subset
MULSD	SSE2
VEX VMULSD	AVX
EVEX VMULSD 128-bit	AVX512F

[AMD Public Use]

MULSS VMULSS Multiply Scalar Single-Precision Floating-Point

Multiplies the single-precision floating-point value in the low-order doubleword of the first source operand by the corresponding value in the low-order doubleword of the second source operand and writes the result into the low-order doubleword of the destination.

There are legacy and extended forms of the instruction:

MULSS

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VMULSS

The extended forms of the instruction have 128-bit encodings only.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [127:32] of the first source operand are copied to bits [127:32] of the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Instruction Support

ORPD VORPD OR Packed Double-Precision Floating-Point

Performs bitwise OR of the of 2, 4, or 8 packed double-precision floating-point values in the second source operand with the corresponding packed double-precision floating-point values in the first source operand, and writes the result into the corresponding elements of the destination.

There are legacy and extended forms of the instruction:

ORPD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VORPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

PABSB VPABSB Packed Absolute Value Signed Byte

Computes the absolute value of sixteen, thirty-two, or sixty-four packed 8-bit signed integers in the source operand. Each byte of the destination receives an unsigned 8-bit integer that is the absolute value of the signed 8-bit integer in the corresponding byte of the source operand.

There are legacy and extended forms of the instruction:

PABSB

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPABSB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. All 32 bytes of the destination are written. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register. All 32 bytes of the destination are written.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

PABSD
VPABSD

Packed Absolute Value Signed Doubleword

Computes the absolute value of four, eight, or sixteen packed 32-bit signed integers in the source operand. Each doubleword of the destination receives an unsigned 32-bit integer that is the absolute value of the signed 32-bit integer in the corresponding doubleword of the source operand.

There are legacy and extended forms of the instruction:

PABSD

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPABSD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a YMM register. All four doublewords of the destination are written. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a ZMM register. All eight doublewords of the destination are written.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

X — SSE, AVX, and AVX2 exception *A — AVX, AVX2 exception* *S — SSE exception*				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

PABSW VPABSW — Packed Absolute Value Signed Word

Computes the absolute value of eight, sixteen, or thirty-two packed 16-bit signed integers in the source operand. Each word of the destination receives an unsigned 16-bit integer that is the absolute value of the signed 16-bit integer in the corresponding word of the source operand.

There are legacy and extended forms of the instruction:

PABSW

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPABSW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. All sixteen words of the destination are written. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register. All thirty-two words of the destination are written.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

PACKSSDW VPACKSSDW — Pack with Signed Saturation Doubleword to Word

Converts four, eight, or sixteen 32-bit signed integers from the first source operand and the second source operand into 16-bit signed integers and packs the results into the destination.

Positive source value greater than 7FFFh are saturated to 7FFFh; negative source values less than 8000h are saturated to 8000h.

Converted values from the first source operand are packed into the low-order words of the destination; converted values from the second source operand are packed into the high-order words of the destination.

There are legacy and extended forms of the instruction:

PACKSSDW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPACKSSDW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and do not support memory fault suppression.

[AMD Public Use]

PACKSSWB VPACKSSWB — Pack with Signed Saturation Word to Byte

Converts eight, sixteen, or thirty-two 16-bit signed integers from the first source operand and the second source operand into 16 or thirty two 8-bit signed integers and packs the results into the destination.

Positive source values greater than 7Fh are saturated to 7Fh; negative source values less than 80h are saturated to 80h.

Converted values from the first source operand are packed into the low-order bytes of the destination; converted values from the second source operand are packed into the high-order bytes of the destination.

There are legacy and extended forms of the instruction:

PACKSSWB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPACKSSWB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and do not support memory fault suppression.

PACKUSDW VPACKUSDW — Pack with Unsigned Saturation Doubleword to Word

Converts four, eight, or sixteen 32-bit signed integers from the first source operand and the second source operand into eight or sixteen 16-bit unsigned integers and packs the results into the destination.

Source values greater than FFFFh are saturated to FFFFh; source values less than 0000h are saturated to 0000h.

Packs converted values from the first source operand into the low-order words of the destination; packs converted values from the second source operand into the high-order words of the destination.

There are legacy and extended forms of the instruction:

PACKUSDW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPACKUSDW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and do not support memory fault suppression.

PACKUSWB VPACKUSWB — Pack with Unsigned Saturation Word to Byte

Converts eight, sixteen, or thirty-two 16-bit signed integers from the first source operand and the second source operand into 16 or thirty two 8-bit unsigned integers and packs the results into the destination.

When a source value is greater than 7Fh it is saturated to FFh; when source value is less than 00h, it is saturated to 00h.

Packs converted values from the first source operand into the low-order bytes of the destination; packs converted values from the second source operand into the high-order bytes of the destination.

There are legacy and extended forms of the instruction:

PACKUSWB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPACKUSWB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and do not support memory fault suppression.

Exceptions

Exception	Mode			Cause of Exception
	Real	Virt	Prot	
Page fault, #PF		S	X	Instruction execution caused a page fault.

X — SSE, AVX, and AVX2 exception
A — AVX, AVX2 exception
S — SSE exception

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

PADDB VPADDB — Packed Add Bytes

Adds 16, 32, or 64 packed 8-bit integer values in the first source operand to corresponding values in the second source operand and writes the integer sums to the corresponding bytes of the destination.

This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 8 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PADDB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPADDB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

[AMD Public Use]

PADDD VPADDD — Packed Add Doublewords

Adds four, eight, or sixteen packed 32-bit integer value in the first source operand to corresponding values in the second source operand and writes integer sums to the corresponding doublewords of the destination.

This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 32 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PADDD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPADDD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

PADDQ VPADDQ Packed Add Quadwords

Adds 2, 4, or 8 packed 64-bit integer values in the first source operand to corresponding values in the second source operand and writes the integer sums to the corresponding quadwords of the destination.

This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 64 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PADDQ

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPADDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Page fault, #PF		S	X	Instruction execution caused a page fault.

X — SSE, AVX, and AVX2 exception
A — AVX, AVX2 exception
S — SSE exception

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

PADDUSB VPADDUSB Packed Add with Unsigned Saturation Bytes

Adds 16, 32, or 64 packed 8-bit unsigned integer values in the first source operand to the corresponding values in the second source operand and writes the unsigned integer sums to the corresponding bytes of the destination.

Sums greater than FFh are saturated to FFh.

There are legacy and extended forms of the instruction:

PADDUSB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPADDUSB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a third ZMM register

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

Instruction Support

PADDW VPADDW — Packed Add Words

Adds 8, 16, or 32 packed 16-bit integer value in the first source operand to the corresponding values in the second source operand and writes the integer sums to the corresponding word of the destination.

This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 16 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PADDW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPADDW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

PALIGNR Packed Align Right
VPALIGNR

For each 128-byte block of the sources/destination, concatenates [source1:source2] in a temporary 256-bit location and right-shifts the concatenated value the number of bytes specified by the unsigned immediate operand. Writes the shifted result to the 128-bit block of the destination.

The binary value of the immediate operand determines the byte shift value. For byte shifts greater than 16 bytes, the upper bytes of the destination are zero-filled; when the byte shift is greater than 32 bytes, the destination is zeroed.

There are two forms of the instruction.

PALIGNR

The first source operand is an XMM register. The second source operand is another XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPALIGNR

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is another XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared. Bits [511:128] of the ZMM register that corresponds to the destination are cleared. One 128-bit block is processed.

YMM Encoding

The first source operand is a YMM register. The second source operand is another YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared. Two 128-bit blocks are processed.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is another ZMM register or a 512-bit memory location. The destination is a third ZMM register. Four 128-bit blocks are processed.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and do not support memory fault suppression.

PAVGB VPAVGB — Packed Average Unsigned Bytes

Computes the rounded averages of 16 or 32 packed unsigned 8-bit integer values in the first source operand and the corresponding values of the second source operand. Writes each average to the corresponding byte of the destination.

An average is computed by adding pairs of 8-bit integer values in corresponding positions in the two operands, adding 1 to a 9-bit temporary sum, and right-shifting the temporary sum by one bit position.

There are legacy and extended forms of the instruction:

PAVGB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPAVGB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

PAVGW VPAVGW — Packed Average Unsigned Words

Computes the rounded average of packed unsigned 16-bit integer values in the first source operand and the corresponding values of the second source operand. Writes each average to the corresponding word of the destination.

An average is computed by adding pairs of 16-bit integer values in corresponding positions in the two operands, adding 1 to a 17-bit temporary sum, and right-shifting the temporary sum by one bit position.

There are legacy and extended forms of the instruction:

PAVGW

The first source operand is an XMM register. The second source operand is an XMM register or 128-bit memory location. The destination is the same XMM register as the first source operand; the upper 128-bits of the corresponding YMM register are not affected.

VPAVGW

The extended form of the instruction has128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

PBLENDVB VPBLENDVB — Variable Blend Packed Bytes

Copies packed bytes from either of two sources to a destination, as specified by a mask operand.

The mask is defined by the most significant bit of each byte of the mask operand. The position of a mask bit corresponds to the position of the most significant bit of a copied value.

- When a mask bit = 0, the specified element of the first source is copied to the corresponding position in the destination.
- When a mask bit = 1, the specified element of the second source is copied to the corresponding position in the destination.

There are legacy and extended forms of the instruction:

PBLENDVB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected. The mask operand is the implicit register XMM0.

VPBLENDVB

The extended form of the instruction has 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The mask operand is a fourth XMM register selected by bits [7:4] of an immediate byte. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. The mask operand is a fourth YMM register selected by bits [7:4] of an immediate byte. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

Instruction Support

[AMD Public Use]

PBLENDW VPBLENDW — Blend Packed Words

Copies packed words from either of two sources to a destination, as specified by an immediate 8-bit mask operand. For the 256-bit form, the same 8-bit mask is applied twice; once to select words to be written to the lower 128 bits of the destination and again to select words to be written to the upper 128 bits of the destination.

Each bit of the mask selects a word from one of the source operands based on the position of the word within the operand. Bit 0 of the mask selects the least-significant word (word 0) to be copied, bit 1 selects the next-most significant word (word 1), and so forth. Bit 7 selects word 7 (the most-significant word for 128-bit operands).

For the 256-bit operands, the mask is reused to select words in the upper 128-bits of the source operands to be copied. Bit 0 of the mask selects word 8, bit 1 selects word 9, and so forth. Finally, bit 7 of the mask selects the word from position 15.

- When a mask bit = 0, the specified element of the first source is copied to the corresponding position in the destination.
- When a mask bit = 1, the specified element of the second source is copied to the corresponding position in the destination.

There are legacy and extended forms of the instruction:

PBLENDW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPBLENDW

The extended form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

[AMD Public Use]

PCLMULQDQ VPCLMULQDQ — Carry-less Multiply Quadwords

Performs a carry-less multiplication of a selected quadword element of the first source operand by a selected quadword element of the second source operand and writes the product to the destination.

Carry-less multiplication, also known as *binary polynomial multiplication*, is the mathematical operation of computing the product of two operands without generating or propagating carries. It is an essential component of cryptographic processing, and typically requires a large number of cycles.

The instruction provides an efficient means of performing the operation and is particularly useful in implementing the Galois counter mode used in the Advanced Encryption Standard (AES). See Appendix A on page 1883 for additional information.

Bits 4 and 0 of an 8-bit immediate byte operand specify which quadword of each source operand to multiply, as follows.

Mnemonic	Imm[0]	Imm[4]	Quadword Operands Selected
(V)PCLMULLQLQDQ	0	0	SRC1[63:0], SRC2[63:0]
(V)PCLMULHQLQDQ	1	0	SRC1[127:64], SRC2[63:0]
(V)PCLMULLQHQDQ	0	1	SRC1[63:0], SRC2[127:64]
(V)PCLMULHQHQDQ	1	1	SRC1[127:64], SRC2[127:64]

Alias mnemonics are provided for the various immediate byte combinations.

There are legacy and extended forms of the instruction:

PCLMULQDQ

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPCLMULQDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

PCMPEQB VPCMPEQB Packed Compare Equal Bytes

Compares 16, 32 or 64 packed byte values in the first source operand to corresponding values in the second source operand and writes the result of each comparison to the corresponding elements in the destination.

There are legacy, VEX-encoded and EVEX-encoded forms of the instruction.

Legacy and VEX-encoded Forms

The destination is an XMM or a YMM register. When values are equal, all 8 bits of the destination element are set; when values are not equal, all 8 bits of the destination element are cleared.

PCMPEQB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPCMPEQB, VEX-Encoded Form

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a third YMM register.

VPCMPEQB, EVEX-encoded Form

The destination is a first mask register ‘k’, updated according to a second mask register ‘k1’. When values are equal, the corresponding bit in the destination mask register is set to 1; when values are not equal, the result is 0. The EVEX form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

Memory fault suppression is supported.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a mask register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a mask register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a mask register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

[AMD Public Use]

[AMD Public Use]

PCMPEQD VPCMPEQD Packed Compare Equal Doublewords

Compares 16, 32 or 64 packed byte values in the first source operand to corresponding values in the second source operand and writes the result of each comparison to the corresponding elements in the destination.

There are legacy, VEX-encoded and EVEX-encoded forms of the instruction.

Legacy and VEX-encoded Forms

The destination is an XMM or a YMM register. When values are equal, all 16 bits of the destination element are set; when values are not equal, all 32 bits of the destination element are cleared.

PCMPEQD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPCMPEQD, VEX-Encoded Form

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

VPCMPEQD, EVEX-encoded Form

The destination is a first mask register ‘k’, updated according to a second mask register ‘k1’. When values are equal, the corresponding bit in the destination mask register is set to 1; when values are not equal, the result is 0. The EVEX form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

Memory fault suppression is supported.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a mask register.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a mask register.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a mask register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

PCMPEQQ VPCMPEQQ — Packed Compare Equal Quadwords

Compares 16, 32 or 64 packed byte values in the first source operand to corresponding values in the second source operand and writes the result of each comparison to the corresponding elements in the destination.

There are legacy, VEX-encoded and EVEX-encoded forms of the instruction.

Legacy and VEX-encoded Forms

The destination is an XMM or a YMM register. When values are equal, all 64 bits of the destination element are set; when values are not equal, all 64 bits of the destination element are cleared.

PCMPEQQ

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPCMPEQQ, VEX-Encoded Form

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register.

VPCMPEQQ, EVEX-encoded Form

The destination is a first mask register ‘k’, updated according to a second mask register ‘k1’. When values are equal, the corresponding bit in the destination mask register is set to 1; when values are not equal, the result is 0. The EVEX form of the instruction has 128-bit, 256-bit, and 512-bit encodings. Memory fault suppression is supported.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a mask register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a mask register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a mask register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

PCMPEQW VPCMPEQW Packed Compare Equal Words

Compares 16, 32 or 64 packed byte values in the first source operand to corresponding values in the second source operand and writes the result of each comparison to the corresponding elements in the destination.

There are legacy, VEX-encoded and EVEX-encoded forms of the instruction.

Legacy and VEX-encoded Forms

The destination is an XMM or a YMM register. When values are equal, all 16 bits of the destination element are set; when values are not equal, all 16 bits of the destination element are cleared.

PCMPEQW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPCMPEQW, VEX-Encoded Form

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a third YMM register.

VPCMPEQW, EVEX-encoded Form

The destination is a first mask register ‘k’, updated according to a second mask register ‘k1’. When values are equal, the corresponding bit in the destination mask register is set to 1; when values are not equal, the result is 0. The EVEX form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

Memory fault suppression is supported.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a mask register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a mask register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a mask register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

PCMPESTRI Packed Compare
VPCMPESTRI Explicit Length Strings Return Index

Compares character string data in the first and second source operands. Comparison operations are carried out as specified by values encoded in the immediate operand. Writes an index to the ECX register.

Source operands are formatted as a packed characters in one of two supported widths: 8 or 16 bits. Characters may be treated as either signed or unsigned values. Each operand has associated with it a separate integer value specifying the length of the string.

The absolute value of the data in the EAX/RAX register represents the length of the character string in the first source operand; the absolute value of the data in the EDX/RDX register represents the length of the character string in the second source operand.

If the absolute value of the data in either register is greater than the maximum string length that fits in 128 bits, the length is set to the maximum: 8, for 16-bit characters, or 16, for 8-bit characters.

The comparison operations between the two operand strings are summarized in an intermediate result—a comparison summary bit vector that is post-processed to produce the final output. Data fields within the immediate byte specify the source data format, comparison type, comparison summary bit vector post-processing, and output option selection.

The index of either the most significant or least significant set bit of the post-processed comparison summary bit vector is returned in ECX. If no bits are set in the post-processed comparison summary bit vector, ECX is set to 16 for source operand strings composed of 8-bit characters or 8 for 16-bit character strings.

See Section 1.5, “String Compare Instructions” for information about source string data format, comparison operations, comparison summary bit vector generation, post-processing, and output selection options.

The rFLAGS are set to indicate the following conditions:

Flag	Condition
CF	Cleared if the comparison summary bit vector is zero; otherwise set.
PF	cleared.
AF	cleared.
ZF	Set if the specified length of the second string is less than the maximum; otherwise cleared.
SF	Set if the specified length of the first string is less than the maximum; otherwise cleared.
OF	Equal to the value of the lsb of the post-processed comparison summary bit vector.

There are legacy and extended forms of the instruction:

PCMPESTRI

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. A result index is written to the ECX register.

VPCMPESTRI

The extended form of the instruction has a 128-bit encoding only.

[AMD Public Use]

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. A result index is written to the ECX register.

[AMD Public Use]

PCMPESTRM Packed Compare
VPCMPESTRM Explicit Length Strings Return Mask

Compares character string data in the first and second source operands. Comparison operations are carried out as specified by values encoded in the immediate operand. Writes a mask value to the YMM0/XMM0 register.

Source operands are formatted as a packed characters in one of two supported widths: 8 or 16 bits. Characters may be treated as either signed or unsigned values. Each operand has associated with it a separate integer value specifying the length of the string.

The absolute value of the data in the EAX/RAX register represents the length of the character string in the first source operand; the absolute value of the data in the EDX/RDX register represents the length of the character string in the second source operand.

If the absolute value of the data in either register is greater than the maximum string length that fits in 128 bits, the length is set to the maximum: 8, for 16-bit characters, or 16, for 8-bit characters.

The comparison operations between the two operand strings are summarized in an intermediate result—a comparison summary bit vector that is post-processed to produce the final output. Data fields within the immediate byte specify the source data format, comparison type, comparison summary bit vector post-processing, and output option selection.

Depending on the output option selected, the post-processed comparison summary bit vector is either zero-extended to 128 bits or expanded into a byte/word-mask and then written to XMM0.

See Section 1.5, “String Compare Instructions” for information about source string data format, comparison operations, comparison summary bit vector generation, post-processing, and output selection options.

The rFLAGS are set to indicate the following conditions:

Flag	Condition
CF	Cleared if the comparison summary bit vector is zero; otherwise set.
PF	cleared.
AF	cleared.
ZF	Set if the specified length of the second string is less than the maximum; otherwise cleared.
SF	Set if the specified length of the first string is less than the maximum; otherwise cleared.
OF	Equal to the value of the lsb of the post-processed summary bit vector.

There are legacy and extended forms of the instruction:

PCMPESTRM

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The mask result is written to the XMM0 register.

VPCMPESTRM

The extended form of the instruction has a 128-bit encoding only.

[AMD Public Use]

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The mask result is written to the XMM0 register. Bits [255:128] of the YMM0 register are cleared.

Instruction Support

Form	Subset
PCMPESTRM	SSE4.2
VEX VPCMPESTRM	AVX

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

PCMPGTB VPCMPGTB Packed Compare Greater Than Signed Bytes

Compares 16, 32 or 64 packed byte values in the first source operand to corresponding values in the second source operand and writes the result of each comparison to the corresponding elements in the destination.

There are legacy, VEX-encoded, and EVEX-encoded forms of the instruction.

Legacy and VEX-encoded Forms

The destination is an XMM or a YMM register. When a value in the first operand is greater than a value in the second operand, all 8 bits of the destination element are set; when a value in the first operand is less than or equal to a value in the second operand, all 8 bits of the destination are cleared.

PCMPGTB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPCMPGTB, VEX-Encoded Form

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a third YMM register.

VPCMPGTB, EVEX-encoded Form

The destination is a first mask register ‘k’, updated according to a second mask register ‘k1’. When a value in the first operand is greater than a value in the second operand, the corresponding bit in the destination mask register is set to 1; when a value in the first operand is less than or equal to a value in the second operand, the corresponding bit in the destination mask register is set to 0. The EVEX form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

Memory fault suppression is supported.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a mask register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a mask register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a mask register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

[AMD Public Use]

[AMD Public Use]

PCMPGTD VPCMPGTD Packed Compare Greater Than Signed Doublewords

Compares 16, 32 or 64 packed byte values in the first source operand to corresponding values in the second source operand and writes the result of each comparison to the corresponding elements in the destination.

There are legacy, VEX-encoded, and EVEX-encoded forms of the instruction.

Legacy and VEX-encoded Forms

The destination is an XMM or a YMM register. When a value in the first operand is greater than a value in the second operand, all 32 bits of the destination element are set; when a value in the first operand is less than or equal to a value in the second operand, all 32 bits of the destination are cleared.

PCMPEQD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPCMPEQD, VEX-Encoded Form

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register.

VPCMPEQD, EVEX-encoded Form

The destination is a first mask register ‘k’, updated according to a second mask register ‘k1’. When a value in the first operand is greater than a value in the second operand, the corresponding bit in the destination mask register is set to 1; when a value in the first operand is less than or equal to a value in the second operand, the corresponding bit in the destination mask register is set to 0. The EVEX form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

Memory fault suppression is supported.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a mask register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a mask register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a mask register.

[AMD Public Use]

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

PCMPGTQ VPCMPGTQ Packed Compare Greater Than Signed Quadwords

Compares 16, 32 or 64 packed byte values in the first source operand to corresponding values in the second source operand and writes the result of each comparison to the corresponding elements in the destination.

There are legacy, VEX-encoded, and EVEX-encoded forms of the instruction.

Legacy and VEX-encoded Forms

The destination is an XMM or a YMM register. When a value in the first operand is greater than a value in the second operand, all 64 bits of the destination element are set; when a value in the first operand is less than or equal to a value in the second operand, all 64 bits of the destination are cleared.

PCMPEQQ

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPCMPEQQ, VEX-Encoded Form

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register.

VPCMPEQQ, EVEX-encoded Form

The destination is a first mask register ‘k’, updated according to a second mask register ‘k1’. When a value in the first operand is greater than a value in the second operand, the corresponding bit in the destination mask register is set to 1; when a value in the first operand is less than or equal to a value in the second operand, the corresponding bit in the destination mask register is set to 0. The EVEX form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

Memory fault suppression is supported.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a mask register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a mask register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a mask register.

[AMD Public Use]

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

PCMPGTW VPCMPGTW Packed Compare Greater Than Signed Words

Compares 16, 32 or 64 packed byte values in the first source operand to corresponding values in the second source operand and writes the result of each comparison to the corresponding elements in the destination.

There are legacy, VEX-encoded, and EVEX-encoded forms of the instruction.

Legacy and VEX-encoded Forms

The destination is an XMM or a YMM register. When a value in the first operand is greater than a value in the second operand, all 16 bits of the destination element are set; when a value in the first operand is less than or equal to a value in the second operand, all 16 bits of the destination are cleared.

PCMPEQW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPCMPEQW, VEX-Encoded Form

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a third YMM register.

VPCMPEQW, EVEX-encoded Form

The destination is a first mask register ‘k’, updated according to a second mask register ‘k1’. When a value in the first operand is greater than a value in the second operand, the corresponding bit in the destination mask register is set to 1; when a value in the first operand is less than or equal to a value in the second operand, the corresponding bit in the destination mask register is set to 0. The EVEX form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

Memory fault suppression is supported.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a mask register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a mask register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a mask register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

PCMPISTRI Packed Compare
VPCMPISTRI Implicit Length Strings Return Index

Compares character string data in the first and second source operands. Comparison operations are carried out as specified by values encoded in the immediate operand. Writes an index to the ECX register.

Source operands are formatted as a packed characters in one of two supported widths: 8 or 16 bits. Characters may be treated as either signed or unsigned values.

Source operand strings shorter than the maximum that can be packed into a 128-bit value are terminated by a null character (value of 0). The characters prior to the null character constitute the string. If the first (lowest indexed) character is null, the string length is 0.

The comparison operations between the two operand strings are summarized in an intermediate result—a comparison summary bit vector that is post-processed to produce the final output. Data fields within the immediate byte specify the source data format, comparison type, comparison summary bit vector post-processing, and output option selection.

The index of either the most significant or least significant set bit of the post-processed comparison summary bit vector is returned in ECX. If no bits are set in the post-processed comparison summary bit vector, ECX is set to 16 for source operand strings composed of 8-bit characters or 8 for 16-bit character strings.

See Section 1.5, “String Compare Instructions” for information about source string data format, comparison operations, comparison summary bit vector generation, post-processing, and output selection options.

The rFLAGS are set to indicate the following conditions:

Flag	Condition
CF	Cleared if the comparison summary bit vector is zero; otherwise set.
PF	cleared.
AF	cleared.
ZF	Set if any byte (word) in the second operand is null; otherwise cleared.
SF	Set if any byte (word) in the first operand is null; otherwise cleared
OF	Equal to the value of the lsb of the post-processed summary bit vector.

There are legacy and extended forms of the instruction:

PCMPISTRI

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. A result index is written to the ECX register.

VPCMPISTRI

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. A result index is written to the ECX register.

[AMD Public Use]

PCMPISTRM VPCMPISTRM — Packed Compare Implicit Length Strings Return Mask

Compares character string data in the first and second source operands. Comparison operations are carried out as specified by values encoded in the immediate operand. Writes a mask value to the YMM0/XMM0 register

Source operands are formatted as a packed characters in one of two supported widths: 8 or 16 bits. Characters may be treated as either signed or unsigned values.

Source operand strings shorter than the maximum that can be packed into a 128-bit value are terminated by a null character (value of 0). The characters prior to the null character constitute the string. If the first (lowest indexed) character is null, the string length is 0.

The comparison operations between the two operand strings are summarized in an intermediate result—a comparison summary bit vector that is post-processed to produce the final output. Data fields within the immediate byte specify the source data format, comparison type, comparison summary bit vector post-processing, and output option selection.

Depending on the output option selected, the post-processed comparison summary bit vector is either zero-extended to 128 bits or expanded into a byte/word-mask and then written to XMM0.

See Section 1.5, “String Compare Instructions” for information about source string data format, comparison operations, comparison summary bit vector generation, post-processing, and output selection options.

The rFLAGS are set to indicate the following conditions:

Flag	Condition
CF	Cleared if the comparison summary bit vector is zero; otherwise set.
PF	cleared.
AF	cleared.
ZF	Set if any byte (word) in the second operand is null; otherwise cleared.
SF	Set if any byte (word) in the first operand is null; otherwise cleared.
OF	Equal to the value of the lsb of the post-processed summary bit vector.

There are legacy and extended forms of the instruction:

PCMPISTRM

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The mask result is written to the XMM0 register.

VPCMPISTRM

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The mask result is written to the XMM0 register. Bits [255:128] of the YMM0 register are cleared.

[AMD Public Use]

Instruction Support

Form	Subset
PCMPISTRM	SSE4.2
VEX VPCMPISTRM	AVX

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

[AMD Public Use]

PEXTRB VPEXTRB — Extract Packed Byte

Extracts a byte from a source register and writes it to an 8-bit memory location, or to the low-order byte of a general-purpose register, with zero-extension to 32 or 64 bits. Bits [3:0] of an immediate byte operand select the byte to be extracted:

Value of imm8 [3:0]	Source Bits Extracted
0000	[7:0]
0001	[15:8]
0010	[23:16]
0011	[31:24]
0100	[39:32]
0101	[47:40]
0110	[55:48]
0111	[63:56]
1000	[71:64]
1001	[79:72]
1010	[87:80]
1011	[95:88]

1101	[111:104]
1110	[119:112]
1111	[127:120]

There are legacy and extended forms of the instruction:

PEXTRB

The source operand is an XMM register and the destination is an 8-bit memory location, or the low-order byte of a general-purpose register. When the destination is a general-purpose register, the extracted byte is zero-extended to 32 or 64 bits.

VPEXTRB

The extended form of the instruction has a 128-bit encoding only.

The source operand is an XMM register and the destination is an 8-bit memory location, or the low-order byte of a general-purpose register. When the destination is a general-purpose register, the extracted byte is zero-extended to 32 or 64 bits.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

[AMD Public Use]

PEXTRD VPEXTRD — Extract Packed Doubleword

Extracts a doubleword from a source register and writes it to an 32-bit memory location, or a 32-bit general-purpose register. Bits [1:0] of an immediate byte operand select the doubleword to be extracted:

Value of imm8 [1:0]	Source Bits Extracted
00	[31:0]
01	[63:32]
10	[95:64]
11	[127:96]

There are legacy and extended forms of the instruction:

PEXTRD

The encoding is the same as PEXTRQ, with REX.W = 0.

The source operand is an XMM register and the destination is an 32-bit memory location, or a 32-bit general-purpose register.

VPEXTRD

The extended form of the instruction has a 128-bit encoding only.

The encoding is the same as VPEXTRQ, with VEX.W = 0.

The source operand is an XMM register and the destination is an 32-bit memory location or a 32-bit general-purpose register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Instruction Support

Form	Subset
PEXTRD	SSE4.1
VEX VPEXTRD	AVX
EVEX VPEXTRD	AVX512DQ

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

[AMD Public Use]

[AMD Public Use]

PEXTRQ Extract
VPEXTRQ Packed Quadword

Extracts a quadword from a source register and writes it to an 64-bit memory location or to a 64-bit general-purpose register. Bit [0] of an immediate byte operand selects the quadword to be extracted:

Value of imm8 [0]	Source Bits Extracted
0	[63:0]
1	[127:64]

There are legacy and extended forms of the instruction:

PEXTRQ

The encoding is the same as PEXTRD, with REX.W = 1.

The source operand is an XMM register and the destination is an 64-bit memory location or a 64-bit general-purpose register.

VPEXTRQ

The extended form of the instruction has a 128-bit encoding only.

The encoding is the same as VPEXTRD, with VEX.W = 1.

The source operand is an XMM register and the destination is an 64-bit memory location or a 64-bit general-purpose register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

VPEXTRW
Extract Packed Word

Extracts a word from a source register and writes it to a 16-bit memory location or to the low-order word of a general-purpose register, with zero-extension to 32 or 64 bits. Bits [3:0] of an immediate byte operand select the word to be extracted:

Value of imm8 [2:0]	Source Bits Extracted
000	[15:0]
001	[31:16]
010	[47:32
011	[63:48]
100	[79:64]
101	[95:80]
110	[111:96]
111	[127:112]

There are legacy and extended forms of the instruction:

PEXTRW

The legacy form of the instruction has SSE2 and SSE4.1 encodings.

The source operand is an XMM register and the destination is the low-order word of a general-purpose register. The extracted word is zero-extended to 32 or 64 bits.

The source operand is an XMM register and the destination is an 16-bit memory location or the low-order word of a general-purpose register. When the destination is a general-purpose register, the extracted word is zero-extended to 32 or 64 bits.

VPEXTRW

The extended form of the instruction has two 128-bit encodings that correspond to the two legacy encodings.

The source operand is an XMM register and the destination is the low-order word of a general-purpose register. The extracted word is zero-extended to 32 or 64 bits.

The source operand is an XMM register and the destination is an 16-bit memory location or the low-order word of a general-purpose register. When the destination is a general-purpose register, the extracted word is zero-extended to 32 or 64 bits.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

[AMD Public Use]

PHADDD VPHADDD Packed Horizontal Add Doubleword

Adds adjacent 32-bit signed integers in each of two source operands and packs the sums into the destination. If a sum overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set) and only the low-order 32 bits of the sum are written in the destination.

Adds the 32-bit signed integer values in bits [63:32] and bits [31:0] of the first source operand and packs the sum into bits [31:0] of the destination; adds the 32-bit signed integer values in bits [127:96] and bits [95:64] of the first source operand and packs the sum into bits [63:32] of the destination. Adds the corresponding values in the second source operand and packs the sums into bits [95:64] and [127:96] of the destination.

Additionally, for the 256-bit form, adds the 32-bit signed integer values in bits [191:160] and bits [159:128] of the first source operand and packs the sum into bits [159:128] of the destination; adds the 32-bit signed integer values in bits [255:224] and bits [223:192] of the first source operand and packs the sum into bits [191:160] of the destination. Adds the corresponding values in the second source operand and packs the sums into bits [223:192] and [255:224] of the destination.

There are legacy and extended forms of the instruction:

PHADDD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination register. Bits [255:128] of the YMM register that corresponds to the destination not affected.

VPHADDD

The extended form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

[AMD Public Use]

PHADDSW VPHADDSW Packed Horizontal Add with Saturation Word

Adds adjacent 16-bit signed integers in each of two source operands, with saturation, and packs the 16-bit signed sums into the destination.

Positive sums greater than 7FFFh are saturated to 7FFFh; negative sums less than 8000h are saturated to 8000h.

For the 128-bit form of the instruction, the following operations are performed:

```
dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.
Ssum() is a function that returns the saturated 16-bit signed sum of its arguments.

dest[15:0] = Ssum(src1[31:16], src1[15:0])
dest[31:16] = Ssum(src1[63:48], src1[47:32])
dest[47:32] = Ssum(src1[95:80], src1[79:64])
dest[63:48] = Ssum(src1[127:112], src1[111:96])
dest[79:64] = Ssum(src2[31:16], src2[15:0])
dest[95:80] = Ssum(src2[63:48], src2[47:32])
dest[111:96] = Ssum(src2[95:80], src2[79:64])
dest[127:112] = Ssum(src2[127:112], src2[111:96])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = Ssum(src1[159:144], src1[143:128])
dest[159:144] = Ssum(src1[191:176], src1[175:160])
dest[175:160] = Ssum(src1[223:208], src1[207:192])
dest[191:176] = Ssum(src1[255:240], src1[239:224])
dest[207:192] = Ssum(src2[159:144], src2[143:128])
dest[223:208] = Ssum(src2[191:176], src2[175:160])
dest[239:224] = Ssum(src2[223:208], src2[207:192])
dest[255:240] = Ssum(src2[255:240], src2[239:224])
```

There are legacy and extended forms of the instruction:

PHADDSW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPHADDSW

The extended form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

PHADDW VPHADDW — Packed Horizontal Add Word

Adds adjacent 16-bit signed integers in each of two source operands and packs the 16-bit sums into the destination. If a sum overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set).

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.

```
dest[15:0] = src1[31:16] + src1[15:0]
dest[31:16] = src1[63:48] + src1[47:32]
dest[47:32] = src1[95:80] + src1[79:64]
dest[63:48] = src1[127:112] + src1[111:96]
dest[79:64] = src2[31:16] + src2[15:0]
dest[95:80] = src2[63:48] + src2[47:32]
dest[111:96] = src2[95:80] + src2[79:64]
dest[127:112] = src2[127:112] + src2[111:96]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = src1[159:144] + src1[143:128]
dest[159:144] = src1[191:176] + src1[175:160]
dest[175:160] = src1[223:208] + src1[207:192]
dest[191:176] = src1[255:240] + src1[239:224]
dest[207:192] = src2[159:144] + src2[143:128]
dest[223:208] = src2[191:176] + src2[175:160]
dest[239:224] = src2[223:208] + src2[207:192]
dest[255:240] = src2[255:240] + src2[239:224]
```

There are legacy and extended forms of the instruction:

PHADDW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPHADDW

The extended form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

PHSUBD VPHSUBD — Packed Horizontal Subtract Doubleword

Subtracts adjacent 32-bit signed integers in each of two source operands and packs the differences into the destination. The higher-order doubleword of each pair is subtracted from the lower-order doubleword.

Subtracts the 32-bit signed integer value in bits [63:32] of the first source operand from the 32-bit signed integer value in bits [31:0] of the first source operand and packs the difference into bits [31:0] of the destination; subtracts the 32-bit signed integer value in bits [127:96] of the first source operand from the 32-bit signed integer value in bits [95:64] of the first source operand and packs the difference into bits [63:32] of the destination. Performs the corresponding operations on pairs of 32-bit signed integer values in the second source operand and packs the differences into bits [95:64] and [127:96] of the destination.

Additionally, for the 256-bit form, subtracts the 32-bit signed integer value in bits [191:160] of the first source operand from the 32-bit signed integer value in bits [159:128] of the first source operand and packs the difference into bits [159:128] of the destination; subtracts the 32-bit signed integer value in bits [255:224] of the first source operand from the 32-bit integer value in bits [223:192] of the first source operand and packs the difference into bits [191:160] of the destination. Performs the corresponding operations on pairs of 32-bit signed integer values in the second source operand and packs the differences into bits [223:192] and [255:224] of the destination.

There are legacy and extended forms of the instruction:

PHSUBD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPHSUBD

The extended form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

Instruction Support

[AMD Public Use]

PHSUBSW VPHSUBSW Packed Horizontal Subtract with Saturation Word

Subtracts adjacent 16-bit signed integers in each of two source operands, with saturation, and packs the differences into the destination. The higher-order word of each pair is subtracted from the lower-order word.

Positive differences greater than 7FFFh are saturated to 7FFFh; negative differences less than 8000h are saturated to 8000h.

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.
Sdiff(A,B) is a function that returns the saturated 16-bit signed difference A − B.

```
dest[15:0] = Sdiff(src1[15:0], src1[31:16])
dest[31:16] = Sdiff(src1[47:32], src1[63:48])
dest[47:32] = Sdiff(src1[79:64], src1[95:80])
dest[63:48] = Sdiff(src1[111:96], src1[127:112])
dest[79:64] = Sdiff(src2[15:0], src2[31:16])
dest[95:80] = Sdiff(src2[47:32], src2[63:48])
dest[111:96] = Sdiff(src2[79:64], src2[95:80])
dest[127:112] = Sdiff(src2[111:96], src2[127:112])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = Sdiff(src1[143:128], src1[159:144])
dest[159:144] = Sdiff(src1[175:160], src1[191:176])
dest[175:160] = Sdiff(src1[207:192], src1[223:208])
dest[191:176] = Sdiff(src1[239:224], src1[255:240])
dest[207:192] = Sdiff(src2[143:128], src2[159:144])
dest[223:208] = Sdiff(src2[175:160], src2[191:176])
dest[239:224] = Sdiff(src2[207:192], src2[223:208])
dest[255:240] = Sdiff(src2[239:224], src2[255:240])
```

There are legacy and extended forms of the instruction:

PHSUBSW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPHSUBSW

The extended form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

[AMD Public Use]

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

PHSUBW VPHSUBW — Packed Horizontal Subtract Word

Subtracts adjacent 16-bit signed integers in each of two source operands and packs the differences into a destination. The higher-order word of each pair is subtracted from the lower-order word.

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.

```
dest[15:0] = src1[15:0] − src1[31:16
dest[31:16] = src1[47:32] − src1[63:48]
dest[47:32] = src1[79:64] − src1[95:80]
dest[63:48] = src1[111:96] − src1[127:112]
dest[79:64] = src2[15:0] − src2[31:16]
dest[95:80] = src2[47:32] − src2[63:48]
dest[111:96] = src2[79:64] − src2[95:80]
dest[127:112] = src2[111:96] − src2[127:112]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = src1[143:128] − src1[159:144]
dest[159:144] = src1[175:160] − src1[191:176]
dest[175:160] = src1[207:192] − src1[223:208]
dest[191:176] = src1[239:224] − src1[255:240]
dest[207:192] = src2[143:128] − src2[159:144]
dest[223:208] = src2[175:160] − src2[191:176]
dest[239:224] = src2[207:192] − src2[223:208]
dest[255:240] = src2[239:224] − src2[255:240]
```

There are legacy and extended forms of the instruction:

PHSUBW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPHSUBW

The extended form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

PINSRB VPINSRB — Packed Insert Byte

Inserts a byte from an 8-bit memory location or the low-order byte of a 32-bit general-purpose register into a destination register. Bits [3:0] of an immediate byte operand select the location where the byte is to be inserted:

Value of imm8 [3:0]	Insertion Location
0000	[7:0]
0001	[15:8]
0010	[23:16]
0011	[31:24]
0100	[39:32]
0101	[47:40]
0110	[55:48]
0111	[63:56]
1000	[71:64]
1001	[79:72]
1010	[87:80]
1011	[95:88]
1100	[103:96]
1101	[111:104]
1110	[119:112]
1111	[127:120]

There are legacy and extended forms of the instruction:

PINSRB

The source operand is an 8-bit memory location or the low-order byte of a 32-bit general-purpose register and the destination an XMM register. The other bytes of the destination are not affected. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPINSRB

The extended form of the instruction has a 128-bit encoding only.

There are two source operands. The first source operand is an 8-bit memory location or the low-order byte of a 32-bit general-purpose register and the second source operand is an XMM register. The destination is a second XMM register. All the bytes of the second source other than the byte that corresponds to the location of the inserted byte are copied to the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

[AMD Public Use]

PINSRD VPINSRD Packed Insert Doubleword

Inserts a doubleword from a 32-bit memory location or a 32-bit general-purpose register into a destination register. Bits [1:0] of an immediate byte operand select the location where the doubleword is to be inserted:

Value of imm8 [1:0]	Insertion Location
00	[31:0]
01	[63:32]
10	[95:64]
11	[127:96]

There are legacy and extended forms of the instruction:

PINSRD

The encoding is the same as PINSRQ, with REX.W = 0.

The source operand is a 32-bit memory location or a 32-bit general-purpose register and the destination an XMM register. The other doublewords of the destination are not affected. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPINSRD

The extended form of the instruction has a 128-bit encoding only.

The encoding is the same as VPINSRQ, with VEX.W = 0.

There are two source operands. The first source operand is a 32-bit memory location or a 32-bit general-purpose register and the second source operand is an XMM register. The destination is a second XMM register. All the doublewords of the second source other than the doubleword that corresponds to the location of the inserted doubleword are copied to the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Instruction Support

Form	Subset
PINSRD	SSE4.1

PINSRQ VPINSRQ — Packed Insert Quadword

Inserts a quadword from a 64-bit memory location or a 64-bit general-purpose register into a destination register. Bit [0] of an immediate byte operand selects the location where the doubleword is to be inserted:

Value of imm8 [0]	Insertion Location
0	[63:0]
1	[127:64]

There are legacy and extended forms of the instruction:

PINSRQ

The encoding is the same as PINSRD, with REX.W = 1.

The source operand is a 64-bit memory location or a 64-bit general-purpose register and the destination an XMM register. The other quadwords of the destination are not affected. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPINSRQ

The extended form of the instruction has a 128-bit encoding only.

The encoding is the same as VPINSRD, with VEX.W = 1.

There are two source operands. The first source operand is a 64-bit memory location or a 64-bit general-purpose register and the second source operand is an XMM register. The destination is a second XMM register. All the quadwords of the second source other than the quadword that corresponds to the location of the inserted quadword are copied to the destination. Bits [255:128] of the YMM register that corresponds to the destination XMM registers are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Instruction Support

[AMD Public Use]

PINSRW VPINSRW — Packed Insert Word

Inserts a word from a 16-bit memory location or the low-order word of a 32-bit general-purpose register into a destination register. Bits [2:0] of an immediate byte operand select the location where the byte is to be inserted:

Value of imm8 [2:0]	Insertion Location
000	[15:0]
001	[31:16]
010	[47:32
011	[63:48]
100	[79:64]
101	[95:80]
110	[111:96]
111	[127:112]

There are legacy and extended forms of the instruction:

PINSRW

The source operand is a 16-bit memory location or the low-order word of a 32-bit general-purpose register and the destination an XMM register. The other words of the destination are not affected. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPINSRW

The extended form of the instruction has a 128-bit encoding only.

There are two source operands. The first source operand is a 16-bit memory location or the low-order word of a 32-bit general-purpose register and the second source operand is an XMM register. The destination is an XMM register. All the words of the second source other than the word that corresponds to the location of the inserted word are copied to the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

PMADDUBSW VPMADDUBSW — Packed Multiply and Add Unsigned Byte to Signed Word

Multiplies and adds sets of two packed 8-bit unsigned values from the first source operand and two packed 8-bit signed values from the second source operand, with signed saturation; writes eight 16-bit sums to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.
Ssum() is a function that returns the saturated 16-bit signed sum of its arguments.

dest[15:0] = Ssum(src1[7:0] * src2[7:0], src1[15:8] * src2[15:8])
dest[31:16] = Ssum(src1[23:16] * src2[23:16], src1[31:24] * src2[31:24])
dest[47:32] = Ssum(src1[39:32] * src2[39:32], src1[47:40] * src2[47:40])
dest[63:48] = Ssum(src1[55:48] * src2[55:48], src1[63:56] * src2[63:56])
dest[79:64] = Ssum(src1[71:64] * src2[71:64], src1[79:72] * src2[79:72])
dest[95:80] = Ssum(src1[87:80] * src2[87:80], src1[95:88] * src2[95:88])
dest[111:96] = Ssum(src1[103:96] * src2[103:96]], src1[111:104] * src2[111:104])
dest[127:112] = Ssum(src1[119:112] * src2[119:112], src1[127:120] * src2[127:120])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = Ssum(src1[135:128] * src2[135:128], src1[143:136] * src2[143:136])
dest[159:144] = Ssum(src1[151:144] * src2[151:144], src1[159:152] * src2[159:152])
dest[175:160] = Ssum(src1[167:160] * src2[167:160], src1[175:168] * src2[175:168])
dest[191:176] = Ssum(src1[183:176] * src2[183:176], src1[191:184] * src2[191:184])
dest[207:192] = Ssum(src1[199:192] * src2[199:192], src1[207:200] * src2[207:200])
dest[223:208] = Ssum(src1[215:208] * src2[215:208], src1[223:216] * src2[223:216])
dest[239:224] = Ssum(src1[231:224] * src2[231:224], src1[239:232] * src2[239:232])
dest[255:240] = Ssum(src1[247:240] * src2[247:240], src1[255:248] * src2[255:248])
```

There are legacy and extended forms of the instruction:

PMADDUBSW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPMADDUBSW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

[AMD Public Use]

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and do not support memory fault suppression.

[AMD Public Use]

PMADDWD VPMADDWD — Packed Multiply and Add Word to Doubleword

Multiplies and adds sets of four packed 16-bit signed values from two source registers; writes four 32-bit sums to the destination.

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.

```
dest[31:0] = (src1[15:0] * src2[15:0]) + (src1[31:16] * src2[31:16])
dest[63:32] = (src1[47:32] * src2[47:32]) + (src1[63:48] * src2[63:48])
dest[95:64] = (src1[79:64] * src2[79:64]) + (src1[95:80] * src2[95:80])
dest[127:96] = (src1[111:96] * src2[111:96]) + (src1[127:112] * src2[127:112])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[159:128] = (src1[143:128] * src2[143:128]) + (src1[159:144] * src2[159:144])
dest[191:160] = (src1[175:160] * src2[175:160]) + (src1[191:176] * src2[191:176])
dest[223:192] = (src1[207:192] * src2[207:192]) + (src1[223:208] * src2[223:208])
dest[255:224] = (src1[239:224] * src2[239:224]) + (src1[255:240] * src2[255:240])
```

When all four of the signed 16-bit source operands in a set have the value 8000h, the 32-bit overflow wraps around to 8000_0000h. There are no other overflow cases.

There are legacy and extended forms of the instruction:

PMADDWD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPMADDWD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

[AMD Public Use]

PMAXSB VPMAXSB Packed Maximum Signed Bytes

Compares each packed 8-bit signed integer value of the first source operand to the corresponding value of the second source operand and writes the numerically greater value into the corresponding byte of the destination.

The 128-bit form of the instruction compares 16 pairs of 8 bit signed integer values; the 256-bit form compares 32 pairs, and the 512-bit form compares 64 pairs.

There are legacy and extended forms of the instruction:

PMAXSB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source operand is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPMAXSB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

X — SSE, AVX, and AVX2 exception *A — AVX, AVX2 exception* *S — SSE exception*				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

PMAXSD VPMAXSD Packed Maximum Signed Doublewords

Compares each packed 32-bit signed integer value of the first source operand to the corresponding value of the second source operand and writes the numerically greater value into the corresponding doubleword of the destination.

The 128-bit form of the instruction compares 4 pairs of 32-bit signed integer values; the 256-bit form compares 8 pairs, and the 512-bit form compares 16 pairs.

There are legacy and extended forms of the instruction:

PMAXSD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPMAXSD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

PMAXUQ VPMAXUQ — Packed Maximum Unsigned Quadwords

Compares each packed 64-bit unsigned integer value of the first source operand to the corresponding value of the second source operand and writes the numerically greater value into the corresponding quadword of the destination. The 128-bit form of the instruction compares 2 pairs of 64-bit unsigned integer values; the 256-bit form compares 4 pairs, and the 512-bit form compares 8 pairs.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

PMINSB VPMINSB Packed Minimum Signed Bytes

Compares each packed 8-bit signed integer value of the first source operand to the corresponding value of the second source operand and writes the numerically lesser value into the corresponding byte of the destination.

The 128-bit form of the instruction compares 16 pairs of 8 bit signed integer values; the 256-bit form compares 32 pairs, and the 512-bit form compares 64 pairs.

There are legacy and extended forms of the instruction:

PMINSB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source operand is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPMINSB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

PMINSW VPMINSW Packed Minimum Signed Words

Compares each packed 16-bit signed integer value of the first source operand to the corresponding value of the second source operand and writes the numerically lesser value into the corresponding word of the destination.

The 128-bit form of the instruction compares 8 pairs of 16-bit signed integer values; the 256-bit form compares 16 pairs, and the 512-bit form compares 32 pairs.

There are legacy and extended forms of the instruction:

PMINSW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPMINSW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

PMINUD VPMINUD — Packed Minimum Unsigned Doublewords

Compares each packed 32-bit unsigned integer value of the first source operand to the corresponding value of the second source operand and writes the numerically lesser value into the corresponding doubleword of the destination. The 128-bit form of the instruction compares 4 pairs of 32-bit unsigned integer values; the 256-bit form compares 8 pairs, and the 512-bit form compares 16 pairs.

There are legacy and extended forms of the instruction:

PMINUD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPMINUD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

PMINUQ VPMINUQ Packed Minimum Unsigned Quadwords

Compares each packed 64-bit unsigned integer value of the first source operand to the corresponding value of the second source operand and writes the numerically lesser value into the corresponding quadword of the destination. The 128-bit form of the instruction compares 2 pairs of 64-bit unsigned integer values; the 256-bit form compares 4 pairs, and the 512-bit form compares 8 pairs.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory locationa broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

PMINUW VPMINUW Packed Minimum Unsigned Words

Compares each packed 16-bit unsigned integer value of the first source operand to the corresponding value of the second source operand and writes the numerically lesser value into the corresponding word of the destination. The 128-bit form of the instruction compares 8 pairs of 16-bit unsigned integer values; the 256-bit form compares 16 pairs, and the 512-bit form compares 32 pairs.

There are legacy and extended forms of the instruction:

PMINUW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPMINUW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

PMOVMSKB VPMOVMSKB — Packed Move Mask Byte

Copies the value of the most-significant bit of each byte element of the source operand to create a 16 or 32 bit mask value, zero-extends the value, and writes it to the destination.

There are legacy and extended forms of the instruction:

PMOVMSKB

The source operand is an XMM register. The destination is a 32-bit general purpose register. The mask is zero-extended to fill the destination register, the mask occupies bits [15:0].

VPMOVMSKB

The extended form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The source operand is an XMM register. The destination is a 64-bit general purpose register. The mask is zero-extended to fill the destination register, the mask occupies bits [15:0].

YMM Encoding

The source operand is a YMM register. The destination is a 64-bit general purpose register. The mask is zero-extended to fill the destination register, the mask occupies bits [31:0]. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

PMOVSXBD VPMOVSXBD — Packed Move with Sign-Extension Byte to Doubleword

Sign-extends four, eight, or sixteen packed 8-bit signed integers in the source operand to 32 bits and writes the packed doubleword signed integers to the destination. If the source operand is a register, the 8-bit signed integers are taken from least-significant bytes of the register.

There are legacy and extended forms of the instruction:

PMOVSXBD

The source operand is an XMM register or a 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPMOVSXBD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register or a 32-bit memory location. The destination is an

XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is an XMM register or a 64-bit memory location. The destination is an

XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is an XMM register or a 128-bit memory location. The destination is a

ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

PMOVSXDQ VPMOVSXDQ Packed Move with Sign-Extension Doubleword to Quadword

Sign-extends two, four, or eight packed 32-bit signed integers in the source operand to 64 bits and writes the packed quadword signed integers to the destination. If the source operand is a register, the 32-bit signed integers are taken from least-significant doublewords of the register.

There are legacy and extended forms of the instruction:

PMOVSXDQ

The source operand is an XMM register or a 64-bit memory location. The destination is an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPMOVSXDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register or a 64-bit memory location. The destination is an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is an XMM register or a 128-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a YMM register or a 256-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

PMOVZXBW Packed Move Byte to Word with Zero-Extension VPMOVZXBW

Zero-extends eight, sixteen, or thirty-two packed 8-bit signed integers in the source operand to 16 bits and writes the packed word positive unsigned integers to the destination. If the source operand is a register, the 8-bit unsigned integers are taken from least-significant bytes of the register.

There are legacy and extended forms of the instruction:

PMOVZXBW

The source operand is an XMM register or a 64-bit memory location. The destination is an XMM register. Bits above 127 of the YMM/ZMM register that corresponds to the destination register are not affected.

VPMOVZXBW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register or a 64-bit memory location. The destination is an XMM register. Bits above 127 of the YMM/ZMM register that corresponds to the destination register are cleared.

YMM Encoding

The source operand is an XMM register or a 128-bit memory location. The destination is a YMM register. Bits above 255 of the ZMM register that corresponds to the destination register are cleared.

ZMM Encoding

The source operand is a YMM register or a 256-bit memory location. The destination is a

ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

PMULDQ Packed Multiply
VPMULDQ Signed Doubleword to Quadword

Multiplies two or four pairs of 32-bit signed integers in the first and second source operands and writes two or four packed quadword signed integer products to the destination.

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.

```
dest[63:0] = (src1[31:0] * src2[31:0])
dest[127:64] = (src1[95:64] * src2[95:64])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[191:128] = (src1[159:128] * src2[159:128])
dest[255:192] = (src1[223:192] * src2[223:192])
```

There are legacy and extended forms of the instruction:

PMULDQ

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPMULDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

PMULHRSW VPMULHRSW Packed Multiply High with Round and Scale Words

Multiplies each packed 16-bit signed value in the first source operand by the corresponding value in the second source operand, truncates the 32-bit product to the 18 most significant bits by right-shifting, then rounds the truncated value by adding 1 to its least-significant bit. Writes bits [16:1] of the sum to the corresponding word of the destination.

There are legacy and extended forms of the instruction:

PMULHRSW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPMULHRSW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

PMULHUW VPMULHUW — Packed Multiply High Unsigned Word

Multiplies each packed 16-bit unsigned value in the first source operand by the corresponding value in the second source operand; writes the high-order 16 bits of each 32-bit product to the corresponding word of the destination.

There are legacy and extended forms of the instruction:

PMULHUW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPMULHUW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

PMULLD VPMULLD — Packed Multiply and Store Low Signed Doubleword

Multiplies four, eight, or sixteen packed 32-bit signed integers in the first source operand by the corresponding values in the second source operand and writes bits [31:0] of each 64-bit product to the corresponding 32-bit element of the destination.

There are legacy and extended forms of the instruction:

PMULLD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPMULLD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

PMULUDQ Packed Multiply
VPMULUDQ Unsigned Doubleword to Quadword

Multiplies two or four pairs of 32-bit unsigned integers in the first and second source operands and writes two or four packed quadword unsigned integer products to the destination.

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.

```
dest[63:0] = (src1[31:0] * src2[31:0])
dest[127:64] = (src1[95:64] * src2[95:64])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[191:128] = (src1[159:128] * src2[159:128])
dest[255:192] = (src1[223:192] * src2[223:192])
```

There are legacy and extended forms of the instruction:

PMULUDQ

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPMULUDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

POR Packed OR
VPOR

Performs a bitwise OR of the first and second source operands and writes the result to the destination. When one or both of a pair of corresponding bits in the first and second operands are set, the corresponding bit of the destination is set; when neither source bit is set, the destination bit is cleared.

There are legacy and extended forms of the instruction:

POR

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPOR

The extended form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared,

[AMD Public Use]

PSADBW VPSADBW Packed Sum of Absolute Differences Bytes to Words

Subtracts the sixteen packed 8-bit unsigned integers in the second source operand from the corresponding values in the first source operand and computes the absolute difference for each subtraction, then computes two unsigned 16-bit integer sums, one for the eight differences that correspond to the upper eight source bytes, and one for the differences that correspond to the lower eight source bytes. Writes the sums to the destination. The unsigned 16-bit integer sum of the differences of the eight bytes in bits [127:64] of the source operands is written to bits [15:0] of the destination; bits [63:16] are cleared. The unsigned 16-bit integer sum of the differences of the eight bytes in bits [63:0] of the source operands is written to bits [79:64] of the destination; bits [127:80] are cleared. This operation is performed per 128-bit block of data available in the source and destination operands.

There are legacy and extended forms of the instruction:

PSADBW

The first source operand is an XMM register, and the second source operand is an XMM register or a 128-bit memory location. The first source XMM register is also the destination. Bits

[512:128] of the YMM/ZMM register that corresponds to the destination are not affected.

VPSADBW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register, and the second source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [512:128] of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register, and the second source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. Bits [512:256] of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register, and the second source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

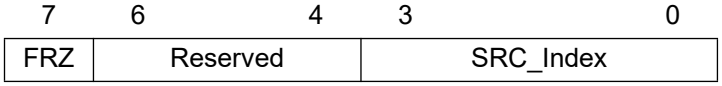
PSHUFB VPSHUFB — Packed Shuffle Byte

Copies bytes from the first source operand to the destination or clears bytes in the destination, as specified by control bytes in the second source operand.

The control bytes occupy positions in the source operand that correspond to positions in the destination. Each control byte has the following fields.



Bits	Description
[7]	Set the bit to clear the corresponding byte of the destination. Clear the bit to copy the selected source byte to the corresponding byte of the destination.
[6:4]	Reserved
[3:0]	Binary value selects the source byte.

For the 256-bit and 512-bit forms of the instruction, the operation is repeated for each 128-bit block, with the operation on each block independent of the other blocks.

There are legacy and extended forms of the instruction:

PSHUFB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSHUFB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and do not support memory fault suppression

[AMD Public Use]

PSHUFD VPSHUFD Packed Shuffle Doublewords

Copies packed doubleword values from a source to a doubleword in the destination, as specified by bit fields of an immediate byte operand. A source doubleword can be copied more than once. For each 128-bit block being processed, source doublewords are selected by two-bit fields in the immediate-byte operand. Each field corresponds to a destination doubleword, as shown:

Destination Doubleword	Immediate-Byte Bit Field	Value of Bit Field	Source Doubleword
[31:0]	[1:0]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[63:32]	[3:2]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[95:64]	[5:4]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[127:96]	[7:6]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]

For the 256-bit and 512-bit forms of the instruction, the operation is repeated for each 128-bit block, with the data in each block independent of the other blocks, but the immediate byte selectors shared between all of the blocks.

There are legacy and extended forms of the instruction:

PSHUFD

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSHUFD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination is an XMM register. The first source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The second source operand is

[AMD Public Use]

an immediate byte. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The second source operand is an immediate byte. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination is a ZMM register. The first source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The second source operand is an immediate byte.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

		11	[127:112]

The word locations in the above table reference the relative location within each 128-bit block being processed.

The least-significant quadword of the source is copied to the corresponding quadword of the destination.

There are legacy and extended forms of the instruction:

PSHUFHW

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSHUFHW

The destination is an XMM register. The first source operand is an XMM register or a 128-bit memory location. The second source operand is an immediate byte.

[AMD Public Use]

Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is a YMM register or a 256-bit memory location. The second source operand is an immediate byte.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination is a ZMM register. The first source operand is a ZMM register or a 512-bit memory location. The second source operand is an immediate byte.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and do not support memory fault suppression.

[AMD Public Use]

PSHUFLW VPSHUFLW — Packed Shuffle Low Words

For each 128-bit block being processed, copies packed word values from the high quadword of the source operand block to a word in the high quadword of the destination block as specified by bit fields of an immediate byte operand. The same immediate byte controls the data copying for each 128-bit block. A source word can be copied more than once. Source words are selected by two-bit fields in the immediate-byte operand. Each bit field corresponds to a destination word, as shown:

Destination Word	Immediate-Byte Bit Field	Value of Bit Field	Source Word
[15:0]	[1:0]	00	[15:0]
		01	[31:16]
		10	[47:32]
		11	[63:48]
[31:16]	[3:2]	00	[15:0]
		01	[31:16]
		10	[47:32]
		11	[63:48]
[47:32]	[5:4]	00	[15:0]
		01	[31:16]
		10	[47:32]
		11	[63:48]
[63:48]	[7:6]	00	[15:0]
		01	[31:16]
		10	[47:32]
		11	[63:48]

The word locations in the above table reference the relative location within each 128-bit block being processed. The most-significant quadword of the source is copied to the corresponding quadword of the destination.

There are legacy and extended forms of the instruction:

PSHUFLW

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSHUFLW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination is an XMM register. The first source operand is an XMM register or a 128-bit memory location. The second source operand is an immediate byte. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

[AMD Public Use]

YMM Encoding

The destination is a YMM register. The first source operand is a YMM register or a 256-bit memory location. The second source operand is an immediate byte. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination is a ZMM register. The first source operand is a ZMM register or a 512-bit memory location. The second source operand is an immediate byte.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and do not support memory fault suppression.

PSIGNB VPSIGNB — Packed Sign Byte

For each packed signed byte in the first source operand, evaluate the corresponding byte of the second source operand and perform one of the following operations.

- When a byte of the second source is negative, write the two's-complement of the corresponding byte of the first source to the destination.
- When a byte of the second source is positive, copy the corresponding byte of the first source to the destination.
- When a byte of the second source is zero, clear the corresponding byte of the destination.

There are legacy and extended forms of the instruction:

PSIGNB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSIGNB

The extended form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

PSLLD VPSLLD Packed Shift Left Logical Doublewords

Left-shifts each packed 32-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination. The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered. Low-order bits emptied by shifting are cleared. When the shift count is greater than 31, the destination is cleared.

There are legacy and extended forms of the instruction:

PSLLD

There are two forms of the instruction, based on the type of count operand. The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSLLD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand. The first source operand is an XMM register. The shift count is specified by either a second XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V' and EVEX.vvvv. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand. The first source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The shift count is specified by either a second YMM register or a 256-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V' and EVEX.vvvv. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

There are two 512-bit encodings. These differ based on the type of count operand. The first source operand is a ZMM register or (for EVEX encodings) a broadcast 32-bit memory location. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a ZMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V' and EVEX.vvvv.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

PSLLDQ VPSLLDQ — Packed Shift Left Logical Double Quadword

Left-shifts the one or each of the two double quadword values in the source operand the number of bytes specified by an immediate byte operand and writes the shifted values to the destination. The immediate byte operand supplies an unsigned shift count. Low-order bytes emptied by shifting are cleared. When the shift value is greater than 15, the destination is cleared. For the 256-bit form of the instruction, the shift count is applied to both the upper and the lower double quadword. Bytes shifted out of the lower 128 bits are not shifted into the upper.

There are legacy and extended forms of the instruction:

PSLLDQ

The source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSLLDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register. The destination is an XMM register specified by VEX.vvvv. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register. The destination is a YMM register specified by VEX.vvvv. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register. The destination is a ZMM register specified by VEX.vvvv.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

PSLLQ VPSLLQ Packed Shift Left Logical Quadwords

Left-shifts each packed 64-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination. The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered. Low-order bits emptied by shifting are cleared. When the shift value is greater than 63, the destination is cleared.

There are legacy and extended forms of the instruction:

PSLLQ

There are two forms of the instruction, based on the type of count operand. The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSLLQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand. The first source operand is an XMM register or (for EVEX encodings) a broadcast 64-bit memory location. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand. The first source operand is a YMM register or (for EVEX encodings) a broadcast 64-bit memory location. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

There are two 512-bit encodings. These differ based on the type of count operand. The first source operand is a ZMM register or (for EVEX encodings) a broadcast 64-bit memory location. The shift count is specified by either a second ZMM register or a 256-bit memory location, or by an immediate 8-bit operand. The destination is a ZMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

PSLLW VPSLLW Packed Shift Left Logical Words

Left-shifts each packed 16-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination. The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered. Low-order bits emptied by shifting are cleared. When the shift count is greater than 15, the destination is cleared.

There are legacy and extended forms of the instruction:

PSLLW

There are two forms of the instruction, based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSLLW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand. The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand. The first source operand is a YMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

There are two 512-bit encodings. These differ based on the type of count operand. The first source operand is a ZMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a ZMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

PSRAD VPSRAD Packed Shift Right Arithmetic Doublewords

Right-shifts each packed 32-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination. The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered. High-order bits emptied by shifting are filled with the sign bit of the initial value. When the shift value is greater than 31, each doubleword of the destination is filled with the sign bit of its initial value.

There are legacy and extended forms of the instruction:

PSRAD

There are two forms of the instruction, based on the type of count operand. The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSRAD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand. The first source operand is an XMM register or (for EVEX encodings) a broadcast 32-bit memory location. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V’ and EVEX.vvvv. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand. The first source operand is a YMM register or (for EVEX encodings) a broadcast 32-bit memory location. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V’ and EVEX.vvvv. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

There are two 512-bit encodings. These differ based on the type of count operand. The first source operand is a ZMM register or (for EVEX encodings) a broadcast 32-bit memory location. The shift count is specified by either a second XMM register or a 128-bit memory location, a broadcast 32-bit memory location (for EVEX encodings), or by an immediate 8-bit operand. The destination is a ZMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V’ and EVEX.vvvv.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

PSRAW VPSRAW Packed Shift Right Arithmetic Words

Right-shifts each packed 16-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination. The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered. High-order bits emptied by shifting are filled with the sign bit of the initial value. When the shift value is greater than 16, each doubleword of the destination is filled with the sign bit of its initial value.

There are legacy and extended forms of the instruction:

PSRAW

There are two forms of the instruction, based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSRAW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand. The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V' and EVEX.vvvv. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand. The first source operand is a YMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V' and EVEX.vvvv. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

There are two 512-bit encodings. These differ based on the type of count operand. The first source operand is a ZMM register. The shift count is specified by either a second ZMM register or a 512-bit memory location, or by an immediate 8-bit operand. The destination is a ZMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V' and EVEX.vvvv.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

PSRLD VPSRLD Packed Shift Right Logical Doublewords

Right-shifts each packed 32-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination. The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered. High-order bits emptied by shifting are cleared. When the shift value is greater than 31, the destination is cleared.

There are legacy and extended forms of the instruction:

PSRLD

There are two forms of the instruction, based on the type of count operand. The first source operand is an XMM register. The shift count is specified by a second XMM register or a 128-bit memory location. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSRLD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand. The first source operand is an XMM register or (for EVEX encodings) a broadcast 32-bit memory location. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V’ and EVEX.vvvv. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand. The first source operand is a YMM register or (for EVEX encodings) a broadcast 32-bit memory location. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V’ and EVEX.vvvv. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

There are two 512-bit encodings. These differ based on the type of count operand. The first source operand is a ZMM register or (for EVEX encodings) a broadcast 32-bit memory location. The shift count is specified by either a second XMM register, a 128-bit memory location, a broadcast 32-bit memory location (for EVEX encodings), or by an immediate 8-bit operand. The destination is a ZMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V’ and EVEX.vvvv.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

PSRLDQ VPSRLDQ Packed Shift Right Logical Double Quadword

Right-shifts one or each of two double quadword values in the source operand the number of bytes specified by an immediate byte operand and writes the shifted values to the destination. The immediate byte operand supplies an unsigned shift count. High-order bytes emptied by shifting are cleared. When the shift value is greater than 15, the destination is cleared. For the 256-bit form of the instruction, the shift count is applied to both the upper and the lower double quadword. Bytes shifted out of the upper 128 bits are not shifted into the lower.

There are legacy and extended forms of the instruction:

PSRLDQ

The source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSRLDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register. The destination is an XMM register specified by VEX.vvvv. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register. The destination is a YMM register specified by VEX.vvvv. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register. The destination is a ZMM register specified by VEX.vvvv.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

PSRLQ VPSRLQ Packed Shift Right Logical Quadwords

Right-shifts each packed 64-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination. The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered. High-order bits emptied by shifting are cleared. When the shift value is greater than 63, the destination is cleared.

There are legacy and extended forms of the instruction:

PSRLQ

There are two forms of the instruction, based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSRLQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand. The first source operand is an XMM register or (for EVEX encodings) a broadcast 64-bit memory location. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V’ and EVEX.vvvv. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand. The first source operand is a YMM register or (for EVEX encodings) a broadcast 64-bit memory location. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V’ and EVEX.vvvv. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

There are two 512-bit encodings. These differ based on the type of count operand. The first source operand is a ZMM register or (for EVEX encodings) a broadcast 64-bit memory location. The shift count is specified by either a second XMM register or a 128-bit memory location, a broadcast 32-bit memory location (for EVEX encodings), or by an immediate 8-bit operand. The destination is a ZMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv or by EVEX.V’ and EVEX.vvvv.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

PSRLW VPSRLW — Packed Shift Right Logical Words

Right-shifts each packed 16-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination. The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered. High-order bits emptied by shifting are cleared. When the shift value is greater than 15, the destination is cleared.

There are legacy and extended forms of the instruction:

PSRLW

There are two forms of the instruction, based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPSRLW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location, or by an immediate 8-bit operand. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location, or by an immediate 8-bit operand. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

PSUBB VPSUBB — Packed Subtract Bytes

Subtracts 16, 32, or 64 packed 8-bit integer values in the second source operand from the corresponding values in the first source operand and writes the integer differences to the corresponding bytes of the destination. This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 8 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PSUBB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPSUBB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

[AMD Public Use]

PSUBD VPSUBD — Packed Subtract Doublewords

Subtracts four, eight, or sixteen packed 32-bit integer values in the second source operand from the corresponding values in the first source operand and writes the integer differences to the corresponding doubleword of the destination. This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 8 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PSUBD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VSUBD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

PSUBQ VPSUBQ Packed Subtract Quadword

Subtracts 2, 4, or 8 packed 64-bit integer values in the second source operand from the corresponding values in the first source operand and writes the differences to the corresponding quadword of the destination. This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 8 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PSUBQ

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VSUBQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

PSUBSB VPSUBSB Packed Subtract Signed With Saturation Bytes

Subtracts 16, 32, or 64 packed 8-bit signed integer value in the second source operand from the corresponding values in the first source operand and writes the signed integer differences to the corresponding byte of the destination. For each packed value in the destination, if the value is larger than the largest signed 8-bit integer, it is saturated to 7Fh, and if the value is smaller than the smallest signed 8-bit integer, it is saturated to 80h.

There are legacy and extended forms of the instruction:

PSUBSB

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPSUBSB

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

PSUBSW VPSUBSW Packed Subtract Signed With Saturation Words

Subtracts 8, 16, or 32 packed 16-bit signed integer values in the second source operand from the corresponding values in the first source operand and writes the signed integer differences to the corresponding word of the destination. Positive differences greater than 7FFFh are saturated to 7FFFh; negative differences less than 8000h are saturated to 8000h.

There are legacy and extended forms of the instruction:

PSUBSW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPSUBSW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

PSUBW VPSUBW — Packed Subtract Words

Subtracts 8, 16, or 32 packed 16-bit integer values in the second source operand from the corresponding values in the first source operand and writes the integer differences to the corresponding word of the destination. This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 8 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PSUBW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VPSUBW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

PUNPCKHBW VPUNPCKHBW — Unpack and Interleave High Bytes

Unpacks the 8 high-order bytes of each octword the first and second source operands and interleaves the bytes as they are copied to the destination. The low-order bytes of each octword of the source operands are ignored. Bytes are interleaved in ascending order from the least-significant byte of the upper 8 bytes of each octword of the source operands with bytes from the first source operand occupying the lower byte of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[7:0] = src1[71:64]
dest[15:8] = src2[71:64]
dest[23:16] = src1[79:72]
dest[31:24] = src2[79:72]
dest[39:32] = src1[87:80]
dest[47:40] = src2[87:80]
dest[55:48] = src1[95:88]
dest[63:56] = src2[95:88]
dest[71:64] = src1[103:96]
dest[79:72] = src2[103:96]
dest[87:80] = src1[111:104]
dest[95:88] = src2[111:104]
dest[103:96] = src1[119:112]
dest[111:104] = src2[119:112]
dest[119:112] = src1[127:120]
dest[127:120] = src2[127:120]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[135:128] = src1[199:192]
dest[143:136] = src2[199:192]
dest[151:144] = src1[207:200]
dest[159:152] = src2[207:200]
dest[167:160] = src1[215:208]
dest[175:168] = src2[215:208]
dest[183:176] = src1[223:216]
dest[191:184] = src2[223:216]
dest[199:192] = src1[231:224]
dest[207:200] = src2[231:224]
dest[215:208] = src1[239:232]
dest[223:216] = src2[239:232]
dest[231:224] = src1[247:240]
dest[239:232] = src2[247:240]
dest[247:240] = src1[255:248]
dest[255:248] = src2[255:248]
```

When the second source operand is all 0s, the destination effectively contains the 8 high-order bytes from the first source operand or the 8 high-order bytes from both octwords of the first source operand zero-extended to 16 bits. This operation is useful for expanding unsigned 8-bit values to unsigned 16-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

[AMD Public Use]

PUNPCKHBW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source operand is also the destination register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPUNPCKHBW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and do not support memory fault suppression.

[AMD Public Use]

PUNPCKHDQ VPUNPCKHDQ — Unpack and Interleave High Doublewords

Unpacks the two high-order doublewords of each octword of the first and second source operands and interleaves the doublewords as they are copied to the destination. The low-order doublewords of each octword of the source operands are ignored. Doublewords are interleaved in ascending order from the least-significant doubleword of the high quadword of each octword with doublewords from the first source operand occupying the lower doubleword of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[31:0] = src1[95:64]
dest[63:32] = src2[95:64]
dest[95:64] = src1[127:96]
dest[127:96] = src2[127:96]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[159:128] = src1[223:192]
dest[191:160] = src2[223:192]
dest[223:192] = src1[255:224]
dest[255:224] = src2[255:224]
```

When the second source operand is all 0s, the destination effectively receives the 2 high-order doublewords from the first source operand or the 2 high-order doublewords from both octwords of the first source operand zero-extended to 64 bits. This operation is useful for expanding unsigned 32-bit values to unsigned 64-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKHDQ

The first source operand is an XMM register. The second source operand is an XMM register or 128-bit memory location. The first source operand is also the destination register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPUNPCKHDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

[AMD Public Use]

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

PUNPCKHQDQ VPUNPCKHQDQ — Unpack and Interleave High Quadwords

Unpacks the high-order quadword of each octword of the first and second source operands and interleaves the quadwords as they are copied to the destination. The low-order quadword of each octword of the source operands is ignored. Quadwords are interleaved in ascending order with the high-order quadword from the first source operand or each octword of the first source operand occupying the lower quadword of corresponding octword of the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[63:0] = src1[127:64]
dest[127:64] = src2[127:64]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[191:128] = src1[255:192]
dest[255:192] = src2[255:192]
```

When the second source operand is all 0s, the destination effectively receives the quadword from upper half of the first sourc4e operand or the high-order quadwords from each octword of the first source operand zero-extended to 128 bits. This operation is useful for expanding unsigned 64-bit values to unsigned 128-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKHQDQ

The first source operand is an XMM register. The second source operand is an XMM register or 128-bit memory location. The first source operand is also the destination register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPUNPCKHQDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

PUNPCKHWD VPUNPCKHWD — Unpack and Interleave High Words

Unpacks the 4 high-order words of each octword of the first and second source operands and interleaves the words as they are copied to the destination. The low-order words of each octword of the source operands are ignored. Words are interleaved in ascending order from the least-significant word of the high quadword of each octword with words from the first source operand occupying the lower word of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[15:0] = src1[79:64]
dest[31:16] = src2[79:64]
dest[47:32] = src1[95:80]
dest[63:48] = src2[95:80]
dest[79:64] = src1[111:96]
dest[95:80] = src2[111:96]
dest[111:96] = src1[127:112]
dest[127:112] = src2[127:112]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = src1[207:192]
dest[159:144] = src2[207:192]
dest[175:160] = src1[223:208]
dest[191:176] = src2[223:208]
dest[207:192] = src1[239:224]
dest[223:208] = src2[239:224]
dest[239:224] = src1[255:240]
dest[255:240] = src2[255:240]
```

When the second source operand is all 0s, the destination effectively receives the 4 high-order words from the first source operand or the 4 high-order words from both octwords of the first source operand zero-extended to 32 bits. This operation is useful for expanding unsigned 16-bit values to unsigned 32-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKHWD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source operand is also the destination register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPUNPCKHWD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

[AMD Public Use]

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

[AMD Public Use]

PUNPCKLBW VPUNPCKLBW — Unpack and Interleave Low Bytes

Unpacks the 8 low-order bytes of each octword of the first and second source operands and interleaves the bytes as they are copied to the destination. The high-order bytes of each octword are ignored. Bytes are interleaved in ascending order from the least-significant byte of source operands with bytes from the first source operand occupying the lower byte of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[7:0] = src1[7:0]
dest[15:8] = src2[7:0]
dest[23:16] = src1[15:8]
dest[31:24] = src2[15:8]
dest[39:32] = src1[23:16]
dest[47:40] = src2[23:16]
dest[55:48] = src1[31:24]
dest[63:56] = src2[31:24]
dest[71:64] = src1[39:32]
dest[79:72] = src2[39:32]
dest[87:80] = src1[47:40]
dest[95:88] = src2[47:40]
dest[103:96] = src1[55:48]
dest[111:104] = src2[55:48]
dest[119:112] = src1[63:56]
dest[127:120] = src2[63:56]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[135:128] = src1[135:128]
dest[143:136] = src2[135:128]
dest[151:144] = src1[143:136]
dest[159:152] = src2[143:136]
dest[167:160] = src1[151:144]
dest[175:168] = src2[151:144]
dest[183:176] = src1[159:152]
dest[191:184] = src2[159:152]
dest[199:192] = src1[167:160]
dest[207:200] = src2[167:160]
dest[215:208] = src1[175:168]
dest[223:216] = src2[175:168]
dest[231:224] = src1[183:176]
dest[239:232] = src2[183:176]
dest[247:240] = src1[191:184]
dest[255:248] = src2[191:184]
```

When the second source operand is all 0s, the destination effectively receives the eight low-order bytes from the first source operand or the eight low-order bytes from both octwords of the first source operand zero-extended to 16 bits. This operation is useful for expanding unsigned 8-bit values to unsigned 16-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

[AMD Public Use]

PUNPCKLBW

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source operand is also the destination register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPUNPCKLBW

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and do not support memory fault suppression.

[AMD Public Use]

PUNPCKLDQ VPUNPCKLDQ — Unpack and Interleave Low Doublewords

Unpacks the two low-order doublewords of each octword of the first and second source operands and interleaves the doublewords as they are copied to the destination. The high-order doublewords of each octword of the source operands are ignored. Doublewords are interleaved in ascending order from the least-significant doubleword of the sources with doublewords from the first source operand occupying the lower doubleword of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[31:0] = src1[31:0]
dest[63:32] = src2[31:0]
dest[95:64] = src1[63:32]
dest[127:96] = src2[63:32]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[159:128] = src1[159:128]
dest[191:160] = src2[159:128]
dest[223:192] = src1[191:160]
dest[255:224] = src2[191:160]
```

When the second source operand is all 0s, the destination effectively receives the two low-order doublewords from the first source operand or the two low-order doublewords from both octwords of the source operand zero-extended to 64 bits. This operation is useful for expanding unsigned 32-bit values to unsigned 64-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKLDQ

The first source operand is an XMM register. The second source operand is an XMM register or 128-bit memory location. The first source operand is also the destination register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPUNPCKLDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

[AMD Public Use]

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

PUNPCKLQDQ VPUNPCKLQDQ — Unpack and Interleave Low Quadwords

Unpacks the low-order quadword of each octword of the first and second source operands and interleaves the quadwords as they are copied to the destination. The high-order quadword of each octword of the source operands is ignored. Quadwords are interleaved in ascending order from the least-significant quadword of the sources with quadwords from the first source operand occupying the lower quadword of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[63:0] = src1[63:0]
dest[127:64] = src2[63:0]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[191:128] = src1[191:128]
dest[255:192] = src2[191:128]
```

When the second source operand is all 0s, the destination effectively receives the low-order quadword from the first source operand or the low-order quadword of both octwords of the first source operand zero-extended to 128 bits. This operation is useful for expanding unsigned 64-bit values to unsigned 128-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKLQDQ

The first source operand is an XMM register. The second source operand is an XMM register or 128-bit memory location. The first source operand is also the destination register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPUNPCKLQDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

PUNPCKLWD VPUNPCKLWD — Unpack and Interleave Low Words

Unpacks the four low-order words of each octword of the first and second source operands and interleaves the words as they are copied to the destination. The high-order words of each octword of the source operands are ignored. Words are interleaved in ascending order from the least-significant word of the source operands with words from the first source operand occupying the lower word of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[15:0] = src1[15:0]
dest[31:16] = src2[15:0]
dest[47:32] = src1[31:16]
dest[63:48] = src2[31:16]
dest[79:64] = src1[47:32]
dest[95:80] = src2[47:32]
dest[111:96] = src1[63:48]
dest[127:112] = src2[63:48]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = src1[143:128]
dest[159:144] = src2[143:128]
dest[175:160] = src1[159:144]
dest[191:176] = src2[159:144]
dest[207:192] = src1[175:160]
dest[223:208] = src2[175:160]
dest[239:224] = src1[191:176]
dest[255:240] = src2[191:176]
```

When the second source operand is all 0s, the destination effectively receives the 4 low-order words from the first source operand or the 4 low-order words of each octword of the first source operand zero-extended to 32 bits. This operation is useful for expanding unsigned 16-bit values to unsigned 32-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKLWD

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source operand is also the destination register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

PUNPCKLWD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

[AMD Public Use]

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

PXOR VPXOR — Packed Exclusive OR

Performs a bitwise XOR of the first and second source operands and writes the result to the destination. When either of a pair of corresponding bits in the first and second operands are set, the corresponding bit of the destination is set; when both source bits are set or when both source bits are not set, the destination bit is cleared.

There are legacy and extended forms of the instruction:

PXOR

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source XMM register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VPXOR

The extended form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

[AMD Public Use]

RCPPS Reciprocal
VRCPPS Packed Single-Precision Floating-Point

Computes the approximate reciprocal of each packed single-precision floating-point value in the source operand and writes the results to the corresponding doubleword of the destination. MXCSR.RC as no effect on the result.

The maximum error is less than or equal to $1.5 * 2^{-12}$ times the true reciprocal. A source value that is ±zero or denormal returns an infinity of the source value sign. Results that underflow are changed to signed zero. For both SNaN and QNaN source operands, a QNaN is returned.

There are legacy and extended forms of the instruction:

RCPPS

Computes four reciprocals. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VRCPPS

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Computes four reciprocals. The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Computes eight reciprocals. The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

[AMD Public Use]

RCPSS Reciprocal
VRCPSS Scalar Single-Precision Floating-Point

Computes the approximate reciprocal of the scalar single-precision floating-point value in a source operand and writes the results to the low-order doubleword of the destination. MXCSR.RC as no effect on the result. The maximum error is less than or equal to $1.5 * 2^{-12}$ times the true reciprocal. A source value that is ±zero or denormal returns an infinity of the source value sign. Results that underflow are changed to signed zero. For both SNaN and QNaN source operands, a QNaN is returned.

There are legacy and extended forms of the instruction:

RCPSS

The source operand is an XMM register or a 32-bit memory location. The destination is an XMM register. Bits [127:32] of the destination are not affected. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VRCPSS

The extended form of the instruction has a 128-bit encoding only.

The first source operand and the destination are XMM registers. The second source operand is an XMM register or a 32-bit memory location. Bits [31:0] of the destination contain the reciprocal; bits [127:32] of the destination are copied from the first source register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

[AMD Public Use]

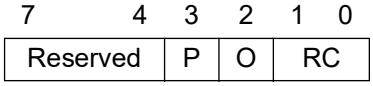
ROUNDPD Round
VROUNDPD Packed Double-Precision Floating-Point

Rounds two or four double-precision floating-point values as specified by an immediate byte operand. Source values are rounded to integral values and written to the destination as double-precision floating-point values.

SNaN source values are converted to QNaN. When DAZ =1, denormals are converted to zero before rounding.

The immediate byte operand is defined as follows.



Bits	Mnemonic	Description
[7:4]	—	Reserved
[3]	P	Precision Exception
[2]	O	Rounding Control Source
[1:0]	RC	Rounding Control

Precision exception definitions:

Value	Description
0	Normal PE exception
1	PE field is not updated. No precision exception is taken when unmasked.

Rounding control source definitions:

Value	Description
0	Use RC from immediate operand
1	Use RC from MXCSR

Rounding control definition:

Value	Description
00	Nearest
01	Downward (toward negative infinity)
10	Upward (toward positive infinity)
11	Truncated

There are legacy and extended forms of the instruction:

ROUNDPD

Rounds two source values. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. There is a third 8-bit immediate operand. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

[AMD Public Use]

VROUNDPD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Rounds two source values. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. There is a third 8-bit immediate operand. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Rounds four source values. The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. There is a third 8-bit immediate operand. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

Precision exception definitions:

Value	Description
0	Normal PE exception
1	PE field is not updated. No precision exception is taken when unmasked.

Rounding control source definitions:

Value	Description
0	Use RC from immediate operand
1	Use RC from MXCSR

Rounding control definition:

Value	Description
00	Nearest
01	Downward (toward negative infinity)
10	Upward (toward positive infinity)
11	Truncated

There are legacy and extended forms of the instruction:

ROUNDSD

The source operand is an XMM register or a 64-bit memory location. When the source is an XMM register, the value to be rounded must be in the low quadword. The destination is an XMM register. There is a third 8-bit immediate operand. Bits [127:64] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to destination XMM register are not affected.

[AMD Public Use]

VROUNDSD

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is an XMM register or a 64-bit memory location. The destination is a third XMM register. There is a fourth 8-bit immediate operand. Bits [127:64] of the destination are copied from the first source operand. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset
ROUNDSD	SSE4.1
VEX VROUNDSD	AVX

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

[AMD Public Use]

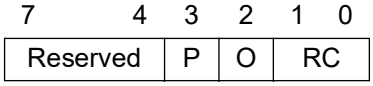
ROUNDSS VROUNDSS — Round Scalar Single-Precision

Rounds a scalar single-precision floating-point value as specified by an immediate byte operand. Source values are rounded to integral values and written to the destination as single-precision floating-point values.

SNaN source values are converted to QNaN. When DAZ =1, denormals are converted to zero before rounding.

The immediate byte operand is defined as follows.



Bits	Mnemonic	Description
[7:4]	—	Reserved
[3]	P	Precision Exception
[2]	O	Rounding Control Source
[1:0]	RC	Rounding Control

Precision exception definitions:

Value	Description
0	Normal PE exception
1	PE field is not updated. No precision exception is taken when unmasked.

Rounding control source definitions:

Value	Description
0	Use RC from immediate operand
1	Use RC from MXCSR

Rounding control definition:

Value	Description
00	Nearest
01	Downward (toward negative infinity)
10	Upward (toward positive infinity)
11	Truncated

There are legacy and extended forms of the instruction:

ROUNDSS

The source operand is an XMM register or a 32-bit memory location. When the source is an XMM register, the value to be rounded must be in the low doubleword. The destination is an XMM register. There is a third 8-bit immediate operand. Bits [127:32] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to destination XMM register are not affected.

[AMD Public Use]

VROUNDSS

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is an XMM register or a 32-bit memory location. The destination is a third XMM register. There is a fourth 8-bit immediate operand. Bits [127:32] of the destination are copied from the first source operand. [AMD Public Use]

RSQRTPS Reciprocal Square Root
VRSQRTPS Packed Single-Precision Floating-Point

Computes the approximate reciprocal of the square root of each packed single-precision floating-point value in the source operand and writes the results to the corresponding doublewords of the destination. MXCSR.RC has no effect on the result.

The maximum error is less than or equal to $1.5 * 2^{-12}$ times the true reciprocal square root. A source value that is ±zero or denormal returns an infinity of the source value sign. Negative source values other than –zero and –denormal return a QNaN floating-point indefinite value. For both SNaN and QNaN source operands, a QNaN is returned.

There are legacy and extended forms of the instruction:

RSQRTPS

Computes four values. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VRSQRTPS

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Computes four values. The destination is an XMM register. The source operand is an XMM register or a 128-bit memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Computes eight values. The destination is a YMM register. The source operand is a YMM register or a 256-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset
RSQRTPS	SSE
VEX VRSQRTPS	AVX

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

[AMD Public Use]

RSQRTSS Reciprocal Square Root
VRSQRTSS Scalar Single-Precision Floating-Point

Computes the approximate reciprocal of the square root of the scalar single-precision floating-point value in a source operand and writes the result to the low-order doubleword of the destination. MXCSR.RC as no effect on the result.

The maximum error is less than or equal to $1.5 * 2^{-12}$ times the true reciprocal square root. A source value that is ±zero or denormal returns an infinity of the source value's sign. Negative source values other than –zero and –denormal return a QNaN floating-point indefinite value. For both SNaN and QNaN source operands, a QNaN is returned.

There are legacy and extended forms of the instruction:

RSQRTSS

The source operand is an XMM register or a 32-bit memory location. The destination is an XMM register. Bits [127:32] of the destination are not affected. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VRSQRTSS

The extended form of the instruction has a 128-bit encoding only.

The first source operand and the destination are XMM registers. The second source operand is an XMM register or a 32-bit memory location. Bits [31:0] of the destination contain the reciprocal square root of the single-precision floating-point value held in bits [31:0] of the second source operand; bits [127:32] of the destination are copied from the first source register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

SHA1RNDS4 Four Rounds of SHA1

Execute 4 rounds of a SHA1 operation using the 4 double words (A, B, C, D) from the first source operand, and value E from the second operand. The lower two bits of the immediate are used to specify the function and constant appropriate for the current round of processing. The resulting (A, B, C, D) is placed in the destination register which is the same as the first source register.

The following function is performed:

```
A ← SRC1[127:96];
B ← SRC1[95:64];
C ← SRC1[63:32];
D ← SRC1[31:0];

W0E ← SRC2[127:96];
W1  ← SRC2[95:64];
W2  ← SRC2[63:32];
W3  ← SRC2[31:0];

i=imm[1:0]  which determines f_i and K_i

First Round operation:
A_1 ← f_ 0(B, C, D) + (A Rotate Left 5) +W0E +K_0;
B_1 ← A;
C_1 ← B Rotate Left 30;
D_1 ← C;
E_1 ← D;

FOR j = 1 to 3
{  A_(j+1) ← f_j(B_j, C_j, D_j) + (A_j Rotate Left 5) +Wj+ E_j +K_i;
   B_(j+1) ← A_j;
   C_(j+1) ← B_j Rotate Left 30;
   D_(j+1) ← C_j;
   E_(j+1) ← D_j;
}
DEST[127:96] ← A_4;
DEST[95:64]  ← B_4;
DEST[63:32]  ← C_4;
DEST[31:0]   ← D_4;
```

SHA256RNDS2 Two Rounds of SHA256

Performs 2 rounds of SHA256 operation with the first operand holding the initial SHA256 state (C, D, G, H), the second operand holding the initial SHA256 state (A, B, E, F), and the implicit operand xmm0 holding a pre-computed sum of the next two double word round 2 message as well as the corresponding round constants. The resulting SHA256 state (A, B, E, F) is placed in the destination register.

SHUFPD VSHUFPD Shuffle Packed Double-Precision Floating-Point

Copies packed double-precision floating-point values from either of two sources to quadwords in the destination, as specified by bit fields of an immediate byte operand. Each bit corresponds to a quadword destination. The 128-bit legacy and extended versions of the instruction use bits [1:0]; the 256-bit extended version uses bits [3:0]; the 512-bit extended version uses bits [7:0], as shown.

Destination Quadword	Immediate-Byte Bit Field	Value of Bit Field	Source 1 Bits Copied	Source 2 Bits Copied
Used by 128-bit, 256-bit, and 512-bit encoding				
[63:0]	[0]	0	[63:0]	—
		1	[127:64]	—
[127:64]	[1]	0	—	[63:0]
		1	—	]127:64]
Used by 256-bit and 512-bit encoding				
[191:128]	[2]	0	[191:128]	—
		1	[255:192]	—
[255:192]	[3]	0	—	[191:128]
		1	—	[255:192]
Used only by 512-bit encoding				
[319:256]	[4]	0	[319:256]	
		1	[383:320]	
[383:320]	[5]	0		[319:256]
		1		[383:320]
[447:384]	[6]	0	[447:384]	
		1	[511:448]	
[511:448]	[7]	0		[447:384]
		1		[511:448]

There are legacy and extended forms of the instruction:

SHUFPD

Selects from four source values. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. There is a third 8-bit immediate operand. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VSHUFPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Selects from four source values. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit

[AMD Public Use]

memory location. The destination is a third XMM register. There is a fourth 8-bit immediate operand. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Selects from four source values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. There is a fourth 8-bit immediate operand. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Selects from four source values. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register. There is a fourth 8-bit immediate operand.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

SHUFPS VSHUFPS Shuffle Packed Single-Precision Floating-Point

Copies packed single-precision floating-point values from either of two sources to doublewords in the destination, as specified by bit fields of an immediate byte operand.

Each bit field corresponds to a doubleword destination. The 128-bit legacy and extended versions of the instruction use a single 128-bit destination; the 256-bit extended version performs duplicate operations on bits [127:0] and bits [255:128] of the source and destination. The 512-bit extended version performs four independent operations, once on each 128-byte block. When more than one 128-bit block is operated on, the same immediate byte bits are used for each block.

Destination Doubleword	Immediate-Byte Bit Field	Value of Bit Field	Source 1 Bits Copied	Source 2 Bits Copied
[31:0]	[1:0]	00	[31:0]	—
		01	[63:32]	—
		10	[95:64]	—
		11	[127:96]	—
[63:32]	[3:2]	00	[31:0]	—
		01	[63:32]	—
		10	[95:64]	—
		11	[127:96]	—
[95:64]	[5:4]	00	—	[31:0]
		01	—	[63:32]
		10	—	[95:64]
		11	—	[127:96]
[127:96]	[7:6]	00	—	[31:0]
		01	—	[63:32]
		10	—	[95:64]
		11	—	[127:96]
Other 128 bit blocks of 256-bit and 512-bit source and destination use the same relative offsets for the source and destination registers, but use the exact same immediate byte bit fields for control				
[159:128]	[1:0]	00	[159:128]	—

[191:160]	[3:2]	00	[159:128]	—
		01	[191:160]	—
		10	[223:192]	—
		11	[255:224]	—
[255:224]	[7:6]	00	—	[159:128]
		01	—	[191:160]
		10	—	[223:192]
		11	—	[255:224]

[AMD Public Use]

There are legacy and extended forms of the instruction:

SHUFPS

Selects from eight source values. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. There is a third 8-bit immediate operand. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VSHUFPS

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Selects from eight source values. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. There is a fourth 8-bit immediate operand. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Selects from 16 source values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. There is a fourth 8-bit immediate operand.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

[AMD Public Use]

SQRTPD Square Root
VSQRTPD Packed Double-Precision Floating-Point

Computes the square root of each packed double-precision floating-point value in a source operand and writes the result to the corresponding quadword of the destination.

Performing the square root of +infinity returns +infinity.

There are legacy and extended forms of the instruction:

SQRTPD

Computes two values. The destination is an XMM register. The source operand is an XMM register or a 128-bit memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VSQRTPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

XMM Encoding

Computes two values. The source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Computes four values. The source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Computes eight values. The source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

SQRTPS VSQRTPS — Square Root Packed Single-Precision Floating-Point

Computes the square root of each packed single-precision floating-point value in a source operand and writes the result to the corresponding doubleword of the destination.

Performing the square root of +infinity returns +infinity.

There are legacy and extended forms of the instruction:

SQRTPS

Computes four values. The destination is an XMM register. The source operand is an XMM register or a 128-bit memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VSQRTPS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

XMM Encoding

Computes four values. The destination is an XMM register. The source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Computes eight values. The destination is a YMM register. The source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Computes sixteen values. The destination is a ZMM register. The source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

SQRTSD Square Root
VSQRTSD Scalar Double-Precision Floating-Point

Computes the square root of a double-precision floating-point value and writes the result to the low quadword of the destination. The three-operand form of the instruction also writes a copy of the upper quadword of a second source operand to the upper quadword of the destination.

Performing the square root of +infinity returns +infinity.

There are legacy and extended forms of the instruction:

SQRTSD

The source operand is an XMM register or a 64-bit memory location. When the source is an XMM register, the source value must be in the low quadword. The destination is an XMM register. Bits [127:64] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to destination XMM register are not affected.

VSQRTSD

The extended form of the instruction has a single 128-bit encoding that requires three operands:

VSQRTSD *xmm1, xmm2, xmm3/mem64*

The first source operand is an XMM register. The second source operand is an XMM register or a 64-bit memory location. When the second source is an XMM register, the source value must be in the low quadword. The destination is a third XMM register. The square root of the second source operand is written to bits [63:0] of the destination register. Bits [127:64] of the destination are copied from the corresponding bits of the first source operand. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

SQRTSS Square Root
VSQRTSS Scalar Single-Precision Floating-Point

Computes the square root of a single-precision floating-point value and writes the result to the low doubleword of the destination. The three-operand form of the instruction also writes a copy of the three most significant doublewords of a second source operand to the upper 96 bits of the destination.

Performing the square root of +infinity returns +infinity.

There are legacy and extended forms of the instruction:

SQRTSS

The source operand is an XMM register or a 32-bit memory location. When the source is an XMM register, the source value must be in the low doubleword. The destination is an XMM register. Bits [127:32] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to destination XMM register are not affected.

VSQRTSS

The extended form has a single 128-bit encoding that requires three operands:

VSQRTSS *xmm1, xmm2, xmm3/mem64*

The first source operand is an XMM register. The second source operand is an XMM register or a 32-bit memory location. When the second source is an XMM register, the source value must be in the low doubleword. The destination is a third XMM register. The square root of the second source operand is written to bits [31:0] of the destination register. Bits [127:32] of the destination are copied from the corresponding bits of the first source operand. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Instruction Support

Form	Subset
SQRTSS	SSE

[AMD Public Use]

SUBPD Subtract
VSUBPD Packed Double-Precision Floating-Point

Subtracts four, eight, or sixteen packed double-precision floating-point values of the first source operand from the corresponding value of the first source operand and writes the difference to the corresponding quadword of the destination.

There are legacy and extended forms of the instruction:

SUBPD

Subtracts two pairs of values.

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VSUBPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Subtracts two pairs of values. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Subtracts four pairs of values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Subtracts eight pairs of values. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

			A	Memory operand not 16-byte aligned when alignment checking enabled.
Page fault, #PF		S	X	Instruction execution caused a page fault.
SIMD floating-point, #XF	S	S	X	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid operation, IE	S	S	X	A source operand was an SNaN value.
	S	S	X	Undefined operation.
Denormalized operand, DE	S	S	X	A source operand was a denormal value.
Overflow, OE	S	S	X	Rounded result too large to fit into the format of the destination operand.
Underflow, UE	S	S	X	Rounded result too small to fit into the format of the destination operand.
Precision, PE	S	S	X	A result could not be represented exactly in the destination format.
X — AVX and SSE exception *A — AVX exception* *S — SSE exception*				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

SUBPS Subtract
VSUBPS Packed Single-Precision Floating-Point

Subtracts four, eight, or sixteen packed single-precision floating-point values in the first source operand from the corresponding value of the first source operand and writes the difference to the corresponding quadword of the destination.

There are legacy and extended forms of the instruction:

SUBPS

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are not affected.

VSUBPS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

SUBSS Subtract
VSUBSS Scalar Single-Precision Floating-Point

Subtracts the single-precision floating-point value in the low-order word of the second source operand from the corresponding value in the first source operand and writes the result to the low-order word of the destination

There are legacy and extended forms of the instruction:

SUBSS

The first source operand is an XMM register. The second source operand is an XMM register or a 32-bit memory location. The first source register is also the destination register. Bits [127:32] of the destination and bits above 127 of the corresponding YMM register are not affected.

VSUBSS

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is an XMM register or a 32-bit memory location. The destination is a third XMM register. Bits [127:32] of the first source operand are copied to bits [127:32] of the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

UCOMISD VUCOMISD Unordered Compare Scalar Double-Precision Floating-Point

Performs an unordered comparison of a double-precision floating-point value in the low-order 64 bits of an XMM register with a double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location.

The ZF, PF, and CF bits in the rFLAGS register reflect the result of the compare as follows.

Result of Compare	ZF	PF	CF
Unordered	1	1	1
Greater Than	0	0	0
Less Than	0	0	1
Equal	1	0	0

The OF, AF, and SF bits in rFLAGS are cleared. If the instruction causes an unmasked SIMD floating-point exception (#XF), the rFLAGS bits are not updated.

The result is unordered when one or both of the operand values is a NaN. UCOMISD signals a SIMD floating-point invalid operation exception (#I) only when a source operand is an SNaN.

The legacy and extended forms of the instruction operate in the same way.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Instruction Support

Form	Subset
UCOMISD	SSE2
VEX VUCOMISD	AVX
EVEX VUCOMISD	AVX512F

[AMD Public Use]

UCOMISS Unordered Compare
VUCOMISS Scalar Single-Precision Floating-Point

Performs an unordered comparison of a single-precision floating-point value in the low-order 32 bits of an XMM register with a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location.

The ZF, PF, and CF bits in the rFLAGS register reflect the result of the compare as follows.

Result of Compare	ZF	PF	CF
Unordered	1	1	1
Greater Than	0	0	0
Less Than	0	0	1
Equal	1	0	0

The OF, AF, and SF bits in rFLAGS are cleared. If the instruction causes an unmasked SIMD floating-point exception (#XF), the rFLAGS bits are not updated.

The result is unordered when one or both of the operand values is a NaN. UCOMISD signals a SIMD floating-point invalid operation exception (#I) only when a source operand is an SNaN.

The legacy and extended forms of the instruction operate in the same way.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

SIMD Floating-Point Exceptions				
Invalid operation, IE	S	S	X	A source operand was an SNaN value.
	S	S	X	Undefined operation.
Denormalized operand, DE	S	S	X	A source operand was a denormal value.

X — AVX and SSE exception
A — AVX exception
S — SSE exception

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

UNPCKHPD VUNPCKHPD Unpack High Double-Precision Floating-Point

Unpacks the high-order double-precision floating-point values of the first and second source operands and interleaves the values into the destination. Bits [63:0] of the source operands are ignored.

Values are interleaved in ascending order from the lsb of the sources and the destination. Bits [127:64] of the first source are written to bits [63:0] of the destination; bits [127:64] of the second source are written to bits [127:64] of the destination. For the 256-bit encoding, the process is repeated for bits [255:192] of the sources and bits [255:128] of the destination. For the 512-bit encoding, the process is repeated three additional times on each 128-bit block.

There are legacy and extended forms of the instruction:

UNPCKHPD

Interleaves one pair of values. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VUNPCKHPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

XMM Encoding

Interleaves one pair of values. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Interleaves two pairs of values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Interleaves four pairs of values. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

[AMD Public Use]

[AMD Public Use]

UNPCKHPS VUNPCKHPS — Unpack High Single-Precision Floating-Point

Unpacks the high-order single-precision floating-point values of the first and second source operands and interleaves the values into the destination. Bits [63:0] of the source operands are ignored.

Values are interleaved in ascending order from the lsb of the sources and the destination. Bits [95:64] of the first source are written to bits [31:0] of the destination; bits [95:64] of the second source are written to bits [63:32] of the destination and so on, ending with bits [127:96] of the second source in bits [127:96] of the destination. For the 256-bit encoding, the process continues for bits [255:192] of the sources and bits [255:128] of the destination. For the 512-bit encoding, the process is repeated three additional times on each 128-bit block.

There are legacy and extended forms of the instruction:

UNPCKHPS

Interleaves two pairs of values. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VUNPCKHPS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

XMM Encoding

Interleaves two pairs of values. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Interleaves four pairs of values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Interleaves eight pairs of values. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

UNPCKLPD VUNPCKLPD — Unpack Low Double-Precision Floating-Point

Unpacks the low-order double-precision floating-point values of the first and second source operands and interleaves the values into the destination. Bits [127:64] of the source operands are ignored. Values are interleaved in ascending order from the lsb of the sources and the destination. Bits [63:0] of the first source are written to bits [63:0] of the destination; bits [63:0] of the second source are written to bits [127:64] of the destination. For the 256-bit encoding, the process is repeated for bits [191:128] of the sources and bits [255:128] of the destination. For the 512-bit encoding, the process is repeated three additional times on each 128-bit block.

There are legacy and extended forms of the instruction:

UNPCKLPD

Interleaves one pair of values. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VUNPCKLPD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

Interleaves one pair of values. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Interleaves two pairs of values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

UNPCKLPS VUNPCKLPS — Unpack Low Single-Precision Floating-Point

Unpacks the low-order single-precision floating-point values of the first and second source operands and interleaves the values into the destination. Bits [127:64] of the source operands are ignored.

Values are interleaved in ascending order from the lsb of the sources and the destination. Bits [31:0] of the first source are written to bits [31:0] of the destination; bits [31:0] of the second source are written to bits [63:32] of the destination and so on, ending with bits [63:32] of the second source in bits [127:96] of the destination. For the 256-bit encoding, the process continues for bits [191:128] of the sources and bits [255:128] of the destination. For the 512-bit encoding, the process is repeated three additional times on each 128-bit block.

There are legacy and extended forms of the instruction:

UNPCKLPS

Interleaves two pairs of values. The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The first source register is also the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

VUNPCKLPS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings.

XMM Encoding

Interleaves two pairs of values. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Interleaves four pairs of values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Interleaves eight pairs of values. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

[AMD Public Use]

VADDPH Add Packed Half-Precision Floating-Point

Adds eight, sixteen, or thirty-two packed half-precision floating-point values in the first source operand to the corresponding values of the second source operand and writes the results into the corresponding word of the destination.

There are only extended forms of the instruction:

VADDPH

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Instruction Support

VADDSH Add Scalar Half-Precision Floating-Point

Adds the half-precision floating-point value in the low-order word of the first source operand to the corresponding value in the low-order word of the second source operand and writes the result into the low-order word of the destination.

There are only extended forms of the instruction:

VADDSH

The extended forms of the instruction have 128-bit encodings only.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [127:32] of the first source operand are copied to bits [127:32] of the destination. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Instruction Support

Exceptions

[AMD Public Use]

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878

[AMD Public Use]

VALIGND Align Doubleword Elements

Concatenates [source1:source2] and right shifts the concatenated values the number of doubleword elements specified by the immediate operand. Writes the shifted result to the destination based on the specified k mask.

Ony the necessary least significant bits of the immediate operand are considered: 2, 3 or 4 bits for XMM, YMM, or ZMM encodings respectively. Other immediate bits above these are ignored.

XMM Encoding

The first source operand is n XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is n YMM register. The second source operand is an XMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is n ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

[AMD Public Use]

VALIGNQ Align Quadword Elements

Concatenates [source1:source2] and right shifts the concatenated values the number of quadword elements specified by the immediate operand. Writes the shifted result to the destination based on the specified k mask.

Only the necessary least significant bits of the immediate operand are considered: 1, 2 or 3 bits for XMM, YMM, or ZMM encodings respectively. Other immediate bits above these are ignored.

XMM Encoding

The first source operand is n XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is n YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is n ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VBLENDMPD Blend Packed Double-Precision Floating Point Elements Based on Mask

Copies packed double-precision floating-point values from either of two sources to a destination, as specified by a mask operand.

Each mask bit specifies a 64-bit element in a source location and a corresponding 64-bit element in the destination register. When a mask bit = 0, the specified element of the first source is copied to the corresponding element in the destination register. When a mask bit = 1, the specified element of the second source is copied to the corresponding element in the destination register.

Note that this instruction does not use the k mask register (specified in EVEX.aaa) in the usual way. The k mask register bits are used to select between source input elements, not determine whether the result element is written. However, the EVEX.z bit maintains its function in that setting EVEX.z causes an output element to be 0 if its corresponding k mask bit is 0.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is an XMM register.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a YMM register.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

VBLENDMPS Blend Packed Single Precision Floating Point Elements Based on Mask

Copies packed single precision floating-point values from either of two sources to a destination, as specified by a mask operand.

Each mask bit specifies a 32-bit element in a source location and a corresponding 64-bit element in the destination register. When a mask bit = 0, the specified element of the first source is copied to the corresponding element in the destination register. When a mask bit = 1, the specified element of the second source is copied to the corresponding element in the destination register.

Note that this instruction does not use the k mask register (specified in EVEX.aaa) in the usual way. The k mask register bits are used to select between source input elements, not determine whether the result element is written. However, the EVEX.z bit maintains its function in that setting EVEX.z causes an output element to be 0 if its corresponding k mask bit is 0.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is an XMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

VBMACOR16X16X16 Bit Matrix Multiply and Accumulate with OR Reduction

Multiply two 16x16 bit matrices using OR reduction and OR the product into a third 16x16 bitmatrix, which is also the destination.

For the 256-bit YMM form, the source registers/memory each contain a single 16X16 (256) bit matrix in bits [255:0], and one matrix multiply/accumulate is performed. For the 512-bit ZMM form, the registers each contain two 16X16 (256) bit matrices in bits [255:0] and [511:255], and two independent matrix multiply/accumulates are performed.

The exact functionality of a bit matrix multiply and accumulate is as follows:

```
for i in 0 to 15
  for j in 0 to 15
    reduction_bit = src1[16*i+j]
    for k in 0 to 15
      reduction_bit |= src2[16*i+k] & src3[16*k+j]
    end for k
    dest[16*i+j] = reduction_bit
  end for j
end for i
```

There are only extended forms of this instruction:

VBMACOR16X16X16

The extended form of the instruction has 256-bit and 512-bit encodings:

YMM Encoding

The first source operand, which is also the destination, is a YMM register. The second source operand, is a YMM register. The third source operand is a YMM register or a 256-bit memory location. Bits above bit 255 of the ZMM register corresponding to the destination are cleared.

ZMM Encoding

The first source operand, which is also the destination, is a ZMM register. The second source operand, is a ZMM register. The third source operand is a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

VBROADCASTF32X2 Broadcast 2 Single-Precision Floating Point Values

Takes 2 single-precision floating point values from an XMM register or a 64-bit memory location and writes them to the 8 or sixteen 32-bit elements of a YMM or ZMM register. The data written is masked per 32-bit element by the mask register.

YMM Encoding
The source operand is a 64-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding
The source operand is a 64-bit memory location. The destination is a ZMM register.
The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Instruction Support

Form	Subset
EVEX VBROADCASTF32X2 256-bit	AVX512VL
EVEX VBROADCASTF32X2 512-bit	AVX512VL, AVX512DQ

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VBROADCASTF32X4 Broadcast 4 Single-Precision Floating Point Values

Loads 4 single-precision floating point values from a 128-bit memory location and writes them to the 8 or sixteen 32-bit elements of a YMM or ZMM register. The data written is masked per 32-bit element by the mask register.

YMM Encoding
The source operand is a 128-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding
The source operand is a 128-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Instruction Support

Form	Subset
EVEX VBROADCASTF32X4 256-bit	AVX512VL
EVEX VBROADCASTF32X4 512-bit	AVX512VL, AVX512F

VBROADCASTSS Load With Broadcast Scalar Single

Loads a single-precision floating-point value from a register or memory and writes it to all 8, 16, or 32doublewords of an XMM, YMM, or ZMM register.

This extended-form instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is the least-significant 32 bits of an XMM register or a 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is the least-significant 32 bits of an XMM register or a 32-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a 32-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Stack, #SS			A	Memory address exceeding stack segment limit or non-canonical.
General protection, #GP			A	Memory address exceeding data segment limit or non-canonical.
			A	Null data segment used to reference memory.
Page fault, #PF			A	Instruction execution caused a page fault.
Alignment check, #AC			A	Unaligned memory reference when alignment checking enabled.
A — AVX, AVX2 exception.				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCMPPH Compare Packed Half-Precision Floating-Point

Compares eight, sixteen, or thirty-two packed half-precision floating-point values of the first source operand to the corresponding values of the second source operand and writes the result of each comparison to the destination. The type of comparison is specified by an immediate byte operand.

Signed comparisons return TRUE only when both operands are valid numbers and the numbers have the relation specified by the type of comparison operation. Ordered comparison returns TRUE when both operands are valid numbers, or FALSE when either operand is a NaN. Unordered comparison returns TRUE only when one or both operands are NaN and FALSE otherwise.

QNaN operands generate an Invalid Operation Exception (IE) only if the comparison type isn't Equal, Unequal, Ordered, or Unordered. SNaN operands always generate an IE.

VCMPPH

The destination is a first mask register ‘k’, updated according to a second mask register ‘k1’. When a comparison is TRUE, the corresponding bit in the destination mask register is set to 1; when a comparison is FALSE, the result is 0.

The extended forms of the instruction have 128-bit, 256-bit, and 512-bit encodings. The upper bits of the destination not written with a comparison result are cleared.

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a mask register.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a mask register.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a mask register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Immediate Operand Encoding

VCMPPH uses bits [4:0] of the 8-bit immediate operand. The following table shows the immediate operand value for the VCMPPS echoes.

Some comparison operations that are not directly supported by immediate-byte encodings can be implemented by swapping the contents of the source and destination operands and executing the appropriate comparison of the swapped values. These additional comparison operations are shown in with the directly supported comparison operations.

[AMD Public Use]

Immediate Operand Value	Compare Operation	Result if NaN Operand	QNaN Operand Causes Invalid Operation Exception
00h, 08h, 10h, 18h	Equal	FALSE	No
01h, 09h, 11h, 19h	Less than	FALSE	Yes
	Greater than (swapped operands)	FALSE	Yes
02h, 0Ah, 12h, 1Ah	Less than or equal	FALSE	Yes
	Greater than or equal (swapped operands)	FALSE	Yes
03h, 0Bh, 13h, 1Bh	Unordered	TRUE	No
04h, 0Ch, 14h, 1Ch	Not equal	TRUE	No
05h, 0Dh, 15h, 1Dh	Not less than	TRUE	Yes
	Not greater than (swapped operands)	TRUE	Yes
06h, 0Eh, 16h, 1Eh	Not less than or equal	TRUE	Yes
	Not greater than or equal (swapped operands)	TRUE	Yes
07h, 0Fh, 17h, 1Fh	Ordered	FALSE	No

The following alias mnemonics for (V)CMPPH with appropriate value of *imm8* are supported.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878

[AMD Public Use]

VCMPSH Compare Scalar Half-Precision Floating-Point

Compares a half-precision floating-point value in the low-order 32 bits of the first source operand with a half-precision floating-point value in the low-order 32 bits of the second source operand and writes the result to the low-order bits of the destination. When a comparison is TRUE, bits of the destination element are set; when a comparison is FALSE, bits of the destination element are cleared.

Comparison type is specified by an immediate byte operand.

Signed comparisons return TRUE only when both operands are valid numbers and the numbers have the relation specified by the type of comparison operation. Ordered comparison returns TRUE when both operands are valid numbers, or FALSE when either operand is a NaN. Unordered comparison returns TRUE only when one or both operands are NaN and FALSE otherwise.

QNaN operands generate an Invalid Operation Exception (IE) only when the comparison type is not Equal, Unequal, Ordered, or Unordered. SNaN operands always generate an IE.

There are only extended forms of the instruction:

VCMPSH

This instruction has extended 128-bit encodings only:

XMM Encoding

The first source operand is an XMM register. The second source operand is another XMM register or a 16-bit memory location. The destination is a K mask register. Bits [63:1] of the destination are cleared. Bit [0] of the destination is set or cleared based on the result of the comparison. Comparison type is specified by bits [4:0] of the immediate byte operand. If a K mask register is specified in EVEX.aaa, bit 0 of that register will be used to mask the result with zero masking the effect is to AND mask bit 0 with the comparison result before it is written to the destination.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Immediate Operand Encoding

VCMPSD uses bits [4:0] of the 8-bit immediate operand. Although VCMPSD supports 20h encoding values, the comparison types echo those of CMPSS on 4-bit boundaries. The following table shows the immediate operand value for CMPSS and each of the VCMPSD echoes.

Some comparison operations that are not directly supported by immediate-byte encodings can be implemented by swapping the contents of the source and destination operands and executing the appropriate comparison of the swapped values. These additional comparison operations are shown with the directly supported comparison operations. When operands are swapped, the first source XMM register is overwritten by the result.

[AMD Public Use]

Immediate Operand Value	Compare Operation	Result if NaN Operand	QNaN Operand Causes Invalid Operation Exception
00h, 08h, 10h, 18h	Equal	FALSE	No

VCOMISH Compare Ordered Scalar Half-Precision Floating-Point

Compares a half-precision floating-point value in the low-order 16 bits of the first operand with a half-precision floating-point value in the low-order 16 bits of the second operand and sets rFLAGS.ZF, PF, and CF to show the result of the comparison:

Comparison	ZF	PF	CF
NaN input	1	1	1
operand 1 > operand 2	0	0	0
operand 1 < operand 2	0	0	1
operand 1 = operand 2	1	0	0

The result is unordered if one or both of the operand values is a NaN. The rFLAGS.OF, AF, and SF bits are cleared. If an #XF SIMD floating-point exception occurs the rFLAGS bits are not updated.
There are only extended forms of the instruction:

VCOMISH

The extended form of the instruction has two 128-bit encodings.
The first source operand is an XMM register. The second source operand is an XMM register or a 16-bit memory location.
The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Instruction Support

[AMD Public Use]

VCOMPRESSPD Compressed Packed Double-Precision Floating Point Data

Select double-precision/single precision floating point elements of the source register whose associated bit of the mask register are ‘1’, and write these selected elements as a single block to the destination. Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select elements of the source, and then the mask value is compressed (by moving all of the ‘1’ bits in the mask down to the lowest bits of the mask) to create a compressed mask to write the destination. When the destination is a register, this compressed mask is used and normal merging masking or zeroing masking occurs. When the destination is memory, this compressed mask is used to write only the selected elements as one block and memory fault suppression is supported, and EVEX.z must be 0.

For example, when compressing the 8 double-precision floating point data elements from a ZMM register, if the K mask register is binary 10001010, the mask bits are “1” for elements 7, 3, and 1. Those elements would be selected from the source register (bits [511:447], [255:192], and [128:64]) and shifted into bits [191:0] to be written to the destination. A compressed mask of binary 00000111 is created, and the data is written to the destination based on this compressed mask. If the destination is a register, bits [191:0] are written and bits [511:192] are merged or zeroed based on EVEX.z. If the destination is memory, 24 bytes (192 bits) are written.

The VEXPANDPD instruction is effectively the opposite of the VCOMPRESS PD/PS instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register. The destination is an XMM register or a 128-bit memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register. The destination is a YMM register or a 256-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register The destination is a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the compressed k mask per 64-bit element as described above and support memory fault suppression based on the compressed k mask.

Instruction Support

Form	Subset
EVEX VCOMPRESSPD 128-bit EVEX VCOMPRESSPD 256-bit	AVX512VL, AVX512F

VCOMPRESSPS Compressed Packed Single-Precision Floating Point Data

Select double-precision/single precision floating point elements of the source register whose associated bit of the mask register are ‘1’, and write these selected elements as a single block to the destination. Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select elements of the source, and then the mask value is compressed (by moving all of the ‘1’ bits in the mask down to the lowest bits of the mask) to create a compressed mask to write the destination. When the destination is a register, this compressed mask is used and normal merging masking or zeroing masking occurs. When the destination is memory, this compressed mask is used to write only the selected elements as one block and memory fault suppression is supported, and EVEX.z must be 0. See the VCOMPRESSPD instruction for an example of how the VCOMPRESSxx instructions work. The VEXPANDPS instruction is effectively the opposite of the VCOMPRESSPD/PS instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register. The destination is an XMM register or a 128-bit memory location. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register. The destination is a YMM register or a 256-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register. The destination is a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the compressed k mask per 32-bit element as described above and support memory fault suppression based on the compressed k mask.

VCVTDQ2PH Convert Packed Doubleword Integers to Packed Half-Precision Floating-Point

Converts packed 32-bit signed integer values to packed half-precision floating-point values and writes the converted values to the destination. When the result is an inexact value, it is rounded as specified by MXCSR.RC.

There are only extended forms of the instruction:

VCVTDQ2PH

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts four packed 32-bit signed integer values in an XMM register, a 128-bit memory location to four packed half-precision floating-point values, or (for EVEX encodings) a broadcast 16-bit memory location and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts eight packed 32-bit signed integer values in a YMM register, a 256-bit memory location to eight half-precision floating-point values, or (for EVEX encodings) a broadcast 16-bit memory location and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts sixteen packed 32-bit signed integer values in a ZMM register or a 512-bit memory location to sixteen packed half-precision floating-point values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

VCVTNE2PS2BF16 Convert Packed Single Precision Floating Point to Packed BFloat16 Floating Point

Converts 8, 16, or 32 packed single precision floating point values from two source registers to packed BFloat16 floating point values and writes the converted values to the destination. The first half of the elements (lower lanes) come from the second source operand. The second half of the elements (higher lanes) come from the first source operand. Individual elements are written or not based on the value in the K mask register. This instruction executes as if MXCSR is 9fc0h, and MXCSR is not updated (that is, rounding uses round-to-nearest rounding mode, input denormals are treated as zero, output denormals are flushed to zero, exceptions are all masked, and no exception bits are generated).

There are only extended forms of this instruction:

VCVTNE2PS2BF16

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts packed single precision floating point values in an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to XMM register values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts packed single precision floating point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to YMM register values, and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts packed single precision floating point values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to ZMM register values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

Instruction Support

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTNEBF162PS Convert Even Lanes of Packed BFloat16 Values to Packed Single Precision Floating Point Values

Convert each even element of the source packed bfloat16 values to a single-precision floating point value. The destination lane corresponds to the source even/odd pair 32-bit lane.
There are only extended forms of this instruction:

VCVTNEBF162PS

The extended form of the instruction has 128-bit and 256-bit encodings:

XMM Encoding

The source is a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the YMM/ZMM register corresponding to the destination are cleared.

YMM Encoding

The source is a 256-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register corresponding to the destination are cleared.

VCVTNEPS2BF16 Convert Packed Single Precision Floating Point to Packed BFloat16 Floating Point

Converts four, eight, or sixteen packed single precision floating point values to packed BFloat16 floating point values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. Instruction executes as if MXCSR is 9fc0h, and MXCSR is not updated (that is, rounding uses round-to-nearest rounding mode, input denormals are treated as zero, output denormals are flushed to zero, exceptions are all masked, and no exception bits are generated).

There are only extended forms of this instruction:

VCVTNEPS2BF16

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts single precision floating point values in an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to BFloat16 floating point values and writes the converted values to an XMM register. Bits [127:64] of the destination and bits above bit 127 of the corresponding ZMM/YMM register are cleared.

YMM Encoding

Converts single precision floating point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to BFloat16 floating point values and writes the converted values to an XMM register. Bits above bit 127 of the ZMM/YMM register corresponding to the destination are cleared.

ZMM Encoding

Converts single precision floating point values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to BFloat16 floating point values and writes the converted values to a YMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VCVTPD2PH Convert Packed Double Precision Floating-Point to Packed Half-Precision Floating-Point

Converts packed double-precision floating-point values to packed half-precision floating-point values and writes the converted values to the low-order doubleword elements of the destination. When the result is an inexact value, it is rounded as specified by MXCSR.RC.

There are only extended forms of the instruction:

VCVTPD2PH

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts two packed double-precision floating-point values in an XMM register, a 128-bit memory location to two packed half-precision floating-point values, or (for EVEX encodings) a broadcast 64-bit memory location and writes the converted values to an XMM register. Bits [127:64] of the destination are cleared. Bits above bit 127 of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts four packed double-precision floating-point values in a YMM register, a 256-bit memory location to four packed half-precision floating-point values, or (for EVEX encodings) a broadcast 64-bit memory location and writes the converted values to a YMM register. Bits [511:128] of the YMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts eight packed 32-bit double-precision floating-point values in a ZMM register or a 512-bit memory location to sixteen packed half-precision floating-point values and writes the converted values to a ZMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VCVTPD2QQ Convert Packed Double Precision Floating Point to Packed Signed Quadword Integer

Converts 2, 4, or 8 packed double precision floating point values to packed signed quadword integer values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is outside the range of an signed quadword (-2^{63} to $+2^{63} - 1$), an invalid-operation exception (IE) is indicated and, if MXCSR.IM masks the IE, the instruction returns the 64-bit indefinite unsigned integer value (8000_0000_0000_0000h).

There are only extended forms of this instruction:

VCVTPD2QQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts double precision floating point values in a(n) XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to signed quadword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts double precision floating point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to signed quadword integer values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts double precision floating point values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to signed quadword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

VCVTPD2UDQ Convert Packed Double Precision Floating Point to Packed Unsigned Doubleword Integer

Converts 2, 4, or 8 packed double precision floating point values to packed unsigned doubleword integer values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is outside the range of an unsigned doubleword (0 to $2^{32} - 1$), an invalid-operation exception (IE) is indicated and, if MXCSR.IM masks the IE, the instruction returns the 32-bit indefinite unsigned integer value (ffff_ffffh).

There are only extended forms of this instruction:

VCVTPD2UDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts double precision floating point values in a(n) XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to unsigned doubleword integer values and writes the converted values to an XMM register. Bits [127:64] of the destination and bits above bit 127 of the corresponding ZMM/YMM register are cleared.

YMM Encoding

Converts double precision floating point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to unsigned doubleword integer values and writes the converted values to an XMM register. Bits above bit 127 of the ZMM/YMM register corresponding to the destination are cleared.

ZMM Encoding

Converts double precision floating point values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to unsigned doubleword integer values and writes the converted values to a YMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTPD2UQQ Convert Packed Double Precision Floating Point to Packed Unsigned Quadword Integer

Converts 2, 4, or 8 packed double precision floating point values to packed unsigned quadword integer values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is outside the range of an unsigned doubleword (0 to $2^{32} - 1$), an invalid-operation exception (IE) is indicated and, if MXCSR.IM masks the IE, the instruction returns the 32-bit indefinite unsigned integer value (ffff_ffffh).

There are only extended forms of this instruction:

VCVTPD2UQQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts double precision floating point values in a(n) XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to unsigned quadword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts double precision floating point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to unsigned quadword integer values and writes the converted values to a YMM register. Bits above bit 255 of the YMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts double precision floating point values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to unsigned quadword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

VCVTPH2DQ Convert Packed Half-Precision Floating-Point to Packed Doubleword Integers

Converts packed half-precision floating-point values to packed signed doubleword integer values and writes the converted values to the destination.

When the result is an inexact value, it is rounded as specified by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (–231 to +231 – 1), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

There are only extended forms of the instruction:

VCVTPH2DQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts four packed half-precision floating-point values in an XMM register, a 64-bit memory location, or (for EVEX encodings) a broadcast 16- bit memory location to four packed signed doubleword integer values and writes the converted values to an XMM register. Bits about bit 127 of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts eight packed half-precision floating-point values in a YMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16- bit memory location to eight packed signed doubleword integer values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts sixteen packed 32-bit signed integer values in a ZMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to sixteen packed signed doubleword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

VCVTPH2PD Convert Packed Half-Precision Floating-Point to Packed Double-Precision Floating-Point

Converts packed half-precision floating-point values to packed double-precision floating-point values and writes the converted values to the destination.

There are only extended forms of the instruction:

VCVTPH2PD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts two packed half-precision floating-point values in the two low order word elements of an XMM register, a 32-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to two double-precision floating-point values, and writes the converted values to an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts four packed half-precision floating-point values in an XMM register, a 64-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to four double-precision floating-point values, and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts eight packed half-precision floating-point values in an XMM register or a 128-bit memory location to eight packed double-precision floating-point values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

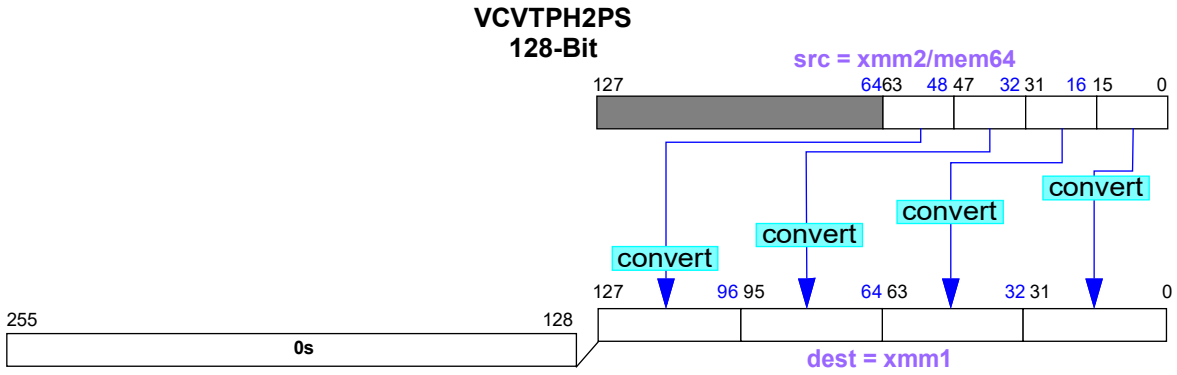
VCVTPH2PS VCVTPH2PSX Convert Packed 16-Bit Floating-Point to Single-Precision Floating-Point

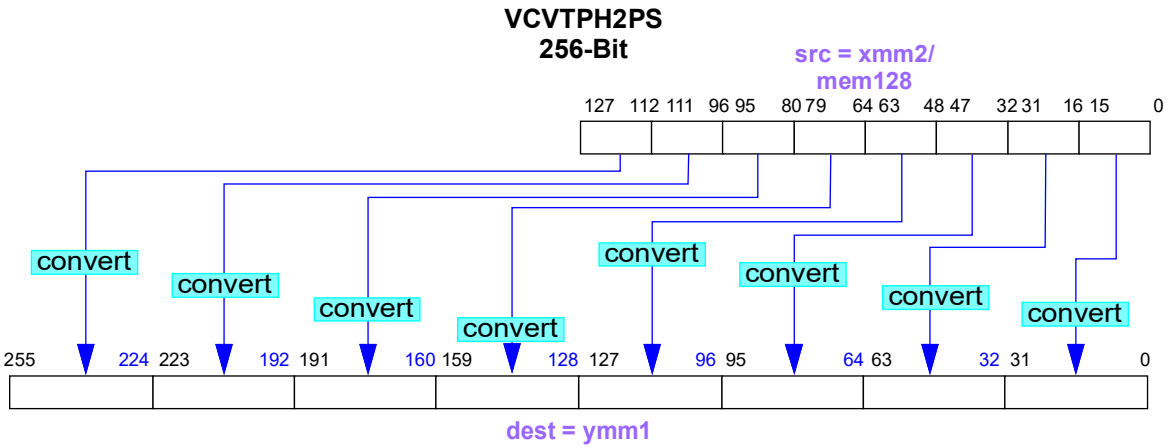
Converts packed half-precision floating point values to single-precision floating point values.

A denormal source operand is converted to a normal result in the destination register. MXCSR.DAZ is ignored. VCVTPH2PS will not report a denormal exception.

Because the full range of 16-bit floating-point encodings, including denormal encodings, can be represented exactly in single-precision format, rounding, inexact results, and denormalized results are not applicable.

The operation of this instruction is illustrated in the following diagram.





This extended-form instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts four packed half-precision floating-point values in the low-order 64 bits of an XMM register or in a 64-bit memory location, or (for EVEX encoded VCVTPH2PSX) a broadcast 16-bit memory location to four packed single-precision floating-point values and writes the converted values to an XMM destination register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

[AMD Public Use]

YMM Encoding

Converts eight packed 16-bit floating-point values in the low-order 128 bits of a YMM register or in a 128-bit memory location to eight packed single-precision floating-point values and writes the converted values to a YMM destination register. Bits [511:128] of the YMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts sixteen packed half-precision floating-point values in a YMM register, a 256-bit memory location, or (for EVEX encoded VCVTPH2PSX) a broadcast 16-bit memory location to sixteen packed single-precision floating-point values and writes the converted values to a ZMM register.

These VCVTPH2PS and VCVTPH2PSX instructions are the same except in two notable areas:

- VCVTPH2PSX has a broadcast form; VCVTPH2PS does not.
- VCVTPH2PSX will report a denormal exception; VCVTPH2PS will not.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Exceptions

Exception	Mode			Cause of Exception
	Real	Virt	Prot	
Invalid opcode, #UD			F	Instruction not supported, as indicated by CPUID feature identifier.
	F	F		AVX instructions are only recognized in protected mode.
			F	CR4.OSXSAVE = 0, indicated by CPUID Fn0000_0001_ECX[OSXSAVE].
			F	XFEATURE_ENABLED_MASK[2:1] ! = 11b.
			F	VEX.W field = 1.
			A	VEX.vvvv ! = 1111b.
			F	REX, F2, F3, or 66 prefix preceding VEX prefix.
			F	Lock prefix (F0h) preceding opcode.
			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 0, see *SIMD Floating-Point Exceptions* below for details.
Device not available, #NM			F	CR0.TS = 1.
Stack, #SS			F	Memory address exceeding stack segment limit or non-canonical.
General protection, #GP			F	Memory address exceeding data segment limit or non-canonical.
			F	Null data segment used to reference memory.
Alignment check, #AC			F	Unaligned memory reference when alignment checking enabled.
Page fault, #PF			F	Instruction execution caused a page fault.
SIMD Floating-Point Exception, #XF			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid-operation exception (IE)			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized-operand exception (DE)			F	A source operand was a denormal value.
Overflow exception (OE)			F	Rounded result too large to fit into the format of the destination operand.
Underflow exception (UE)			F	Rounded result too small to fit into the format of the destination operand.
Precision exception (PE)			F	A result could not be represented exactly in the destination format.
F — F16C exception.				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTPH2QQ Convert Packed Half-Precision Floating-Point to Packed Signed Quadword Integer

Converts four, eight, or sixteen packed half-precision floating point values to packed signed quadword integer values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is outside the range of a signed quadword (-263 to +263 – 1), an invalidoperation exception (IE) is indicated and, if MXCSR.IM masks the IE, the instruction returns the 64-bit indefinite signed integer value (8000_0000_0000_0000h).

There are only extended forms of this instruction:

VCVTPH2QQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts packed half-precision floating point values in a(n) XMM register, a 64-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to signed quadword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts packed half-precision floating point values in an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to signed quadword integer values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts packed half-precision floating point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to signed quadword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

XMM Encoding

Converts half-precision floating point values in an XMM register, a 32-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to unsigned quadword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts half-precision floating point values in an XMM register, a 64-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to unsigned quadword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts half-precision floating point values in an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to unsigned quadword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTPH2UW Convert Packed Half-Precision Floating-Point to Packed Unsigned Word Integers

Converts packed half-precision floating-point values to packed unsigned word integer values and writes the converted values to the destination.

When the result is an inexact value, it is rounded as specified by MXCSR.RC or by the explicit rounding control bits in the instruction. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed word (0 to $+2^{16}$ -1), the instruction returns the 16-bit indefinite unsigned integer value (ffffh) when the invalid-operation exception (IE) is masked.

There are only extended forms of the instruction.

VCVTPH2W

The extended forms of the instruction have 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts eight half-precision floating-point values in second source XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit unsigned integer values and writes the converted values to the destination XMM register.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts sixteen half-precision floating-point values in second source YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit unsigned integer values and writes the converted values to the destination YMM register.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts thirty-two half-precision floating-point values in second source ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit unsigned integer values and writes the converted values to the destination ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VCVTPH2W Convert Packed Half-Precision Floating-Point to Packed Signed Word Integers

Converts packed half-precision floating-point values to packed signed word integer values and writes the converted values to the destination.

When the result is an inexact value, it is rounded as specified by MXCSR.RC or by the explicit rounding control bits in the instruction. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed word (-2^{15} to $+2^{15} - 1$), the instruction returns the 16-bit indefinite signed integer value (8000h) when the invalid-operation exception (IE) is masked.

There are only extended forms of the instruction.

VCVTPH2W

The extended forms of the instruction have 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts eight half-precision floating-point values in the source XMM register, 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit signed integer values and writes the converted values to the destination XMM register.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts sixteen half-precision floating-point values in second source YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit signed integer values and writes the converted values to the destination YMM register.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts thirty-two half-precision floating-point values in second source ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit signed integer values and writes the converted values to the destination ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

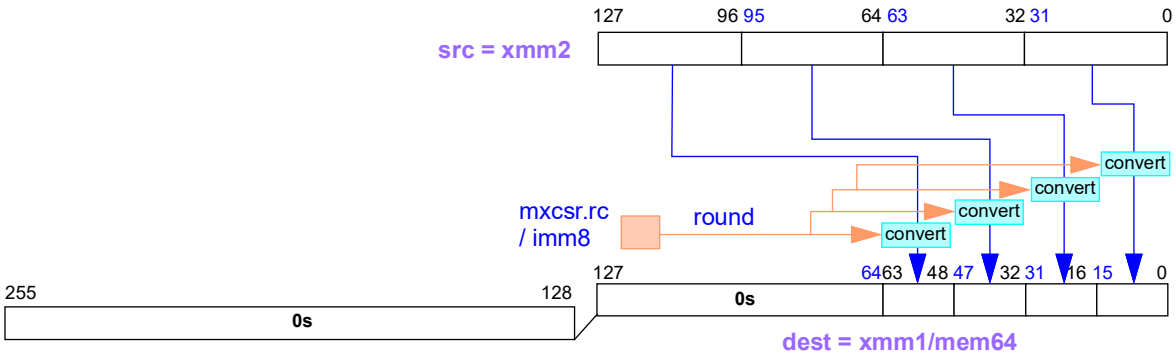
[AMD Public Use]

VCVTPS2PH VCVTPS2PHX Convert Packed Single-Precision Floating-Point to 16-Bit Floating-Point

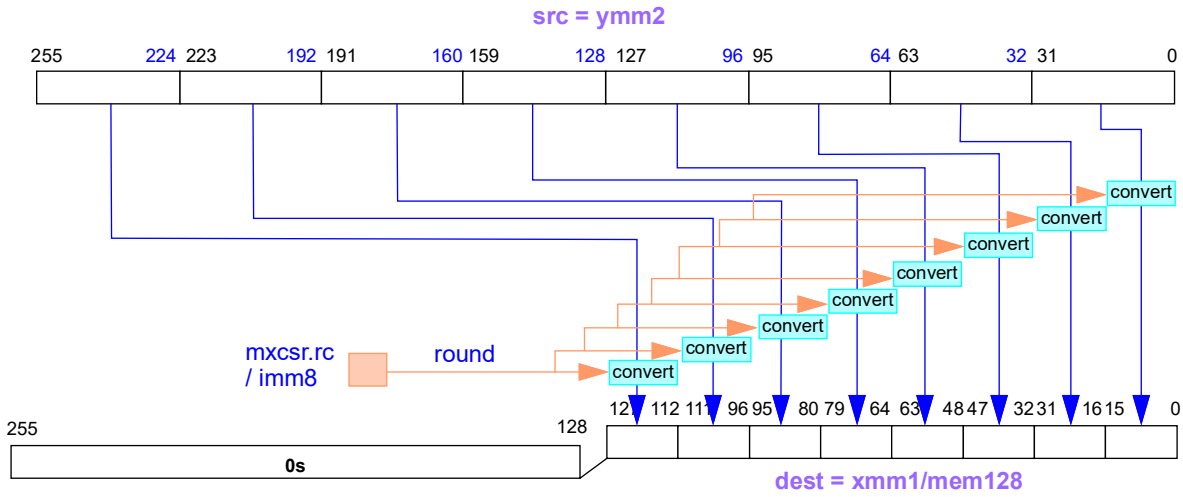
Converts packed single-precision floating-point values to packed 16-bit floating-point values and writes the converted values to the destination register or to memory.

The operation of this instruction is illustrated in the following diagram.

VCVTPS2PH 128-Bit



VCVTPS2PH 256-Bit



The differences between the VCVTPS2PH and VCVTPS2PHX instructions are as follows:

- VCVTPS2PH has store forms, not load forms. VCVTPS2PHX does not have store forms, but does have load forms, including broadcasting forms.
- VCVTPS2PH has an immediate operand that may be used for the rounding control. VCVTPS2PHX will always use MXCSR.RC for the rounding control.

[AMD Public Use]

For VCVTPS2PH, the handling of rounding is controlled by fields in the immediate byte, as shown in the following table.

Rounding Control with Immediate Byte Operand

Mnemonic	Rounding Source (RS)	Rounding Control (RC)		Description	Notes
Bit	**2**	**1**	**0**		
Value	0	0	0	Nearest	Ignore MXCSR.RC.
		0	1	Down	
		1	0	Up	
		1	1	Truncate	
	1	X	X	Use MXCSR.RC for rounding.	

MXCSR[FTZ] has no effect on these instructions. Values within the half-precision denormal range are unconditionally converted to denormals.

This extended-form instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts four packed single-precision floating-point values in an XMM register to four packed 16-bit floating-point values and writes the converted values to the 64-bit destination. Bits above bit 63 of the ZMM/YMM/XMM register that corresponds to the destination are cleared.

YMM Encoding

Converts eight packed single-precision floating-point values in a YMM register to eight packed 16-bit floating-point values and writes the converted values to the 128 bits of the destination. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts sixteen packed single-precision floating-point values in a ZMM register or a 512-bit memory location to sixteen packed 16-bit floating-point values and writes the converted values to the 256 bits of the destination. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VCVTPS2QQ Convert Packed Single Precision Floating-Point to Packed Signed Quadword Integer

Converts 2, 4, or 8 packed single precision floating point values to packed signed quadword integer values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is outside the range of a signed quadword (-263 to +263 – 1), an invalid-operation exception (IE) is indicated and, if MXCSR.IM masks the IE, the instruction returns the 64-bit indefinite signed integer value (8000_0000_0000_0000h).

There are only extended forms of this instruction:

VCVTPS2QQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts packed single precision floating point values in a(n) XMM register, a 64-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to signed quadword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts packed single precision floating point values in an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to signed quadword integer values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts packed single precision floating point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to signed quadword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

VCVTPS2UDQ Convert Packed Single Precision Floating Point to Packed Unsigned Doubleword Integer

Converts four, eight, or sixteen packed single precision floating point values to packed unsigned doubleword integer values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is outside the range of an unsigned quadword (0 to $2^{32} - 1$), an invalid-operation exception (IE) is indicated and, if MXCSR.IM masks the IE, the instruction returns the 32-bit indefinite unsigned integer value (ffff_ffffh).

There are only extended forms of this instruction:

VCVTPS2UDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts packed single precision floating point values in a(n) XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to unsigned doubleword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts packed single precision floating point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to unsigned doubleword integer values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts packed single precision floating point values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to unsigned doubleword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

VCVTQQ2PD Convert Packed Signed Quadword Integer to Packed Double Precision Floating Point

Converts 2, 4, or 8 packed signed quadword integer values to packed double precision floating point values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC.

There are only extended forms of this instruction:

VCVTQQ2PD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts signed quadword integer values in a(n) XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to double precision floating point values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts signed quadword integer values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to double precision floating point values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts signed quadword integer values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to double precision floating point values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTQQ2PH Convert Packed Signed Quadword Integer to Packed Half-Precision Floating Point

Converts two, four, or eight packed signed quadword integer values to packed half-precision floating point values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC.

There are only extended forms of this instruction:

VCVTQQ2PH

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts signed quadword integer values in a(n) XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to half-precision floating point values and writes the converted values to an XMM register. Bits [127:32] of the destination and bits above bit 127 of the corresponding ZMM/YMM register are cleared.

YMM Encoding

Converts signed quadword integer values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to half-precision floating point values and writes the converted values to an XMM register. Bits [127:64] of the destination and bits above bit 127 of the ZMM/YMM register corresponding to the destination are cleared.

ZMM Encoding

Converts signed quadword integer values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to half-precision floating point values and writes the converted values to a XMM register. Bits above bit 127 of the ZMM/YMM register corresponding to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VCVTSD2USI Convert Scalar Double-Precision Floating-Point to Unsigned Doubleword or Quadword Integer

Converts a scalar double-precision floating-point value to a 32-bit or 64-bit unsigned integer value and writes the converted value to a general-purpose register.

When the result of the conversion is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is outside the maximum unsigned doubleword (0 to 2^{32}–1) or quadword (0 to 2^{64}–1) range, the instruction returns the unsigned indefinite integer value (ffff_ffffh for 32-bit integers, ffff_ffff_ffff_ffffh for 64-bit integers) when the invalid-operation exception (IE) is masked.

There are only extended forms of the instruction:

VCVTSD2USI

The extended form of the instruction has two 128-bit encodings:

- In non 64-bit modes, or in 64-bit mode when EVEX.W = 0, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 32-bit unsigned integer and writes the converted value to a 32-bit general purpose register.
- In 64-bit mode when EVEX.W = 1, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 64-bit unsigned integer and writes the converted value to a 64-bit general purpose register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Instruction Support

[AMD Public Use]

VCVTSH2SI Convert Scalar Half-Precision Floating-Point to Signed Doubleword or Quadword Integer

Converts a half-precision floating-point value to a signed integer value and writes the converted value to a general-purpose register.

When the result of the conversion is an inexact value, the value is rounded as specified by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (–231 to +231 – 1) or quadword value (–263 to +263 – 1), the indefinite integer value (8000_0000h for 32-bit integers, 8000_0000_0000_0000h for 64-bit integers) is returned when the invalid-operation exception (IE) is masked.

There are only extended forms of the instruction:

VCVTSH2SI

The extended form of the instruction has two 128-bit encodings.

- In non-64-bit modes, or in 64-bit mode when (E)VEX.W = 0, converts a half-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 32-bit signed integer value and writes the converted value to a 32-bit general-purpose register.
- In 64-bit mode when (E)VEX.W = 1, converts a half-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 64-bit signed integer value and writes the converted value to a 64-bit general-purpose register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTSI2SH Convert Signed Doubleword or Quadword Integer to Scalar Half-Precision Floating-Point

Converts a signed integer value to a half-precision floating-point value and writes the converted value to an XMM register. When the result of the conversion is an inexact value, the value is rounded as specified by {er} (if specified) or by MXCSR.RC.

There are only extended forms of the instruction:

VCVTSI2SH

The extended form of the instruction has two 128-bit encodings.

- In non-64-bit modes, or in 64-bit mode when (E)VEX.W = 0, converts a signed doubleword integer value from a 32-bit source general-purpose register or a 32-bit memory location (the second source operand) to a half-precision floating-point value and writes the converted value to the low-order 16 bits of the destination XMM register. Bits [127:16] of the first source XMM register are copied to the destination XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.
- In 64-bit mode when (E)VEX.W = 1, converts a signed quadword integer value from a 64-bit source general-purpose register or a 64-bit memory location (the second source operand) to a half-precision floating-point value and writes the converted value to the low-order 16 bits of the destination XMM register. Bits [127:16] of the first source XMM register are copied to the destination XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTSS2SH Convert Scalar Single-Precision Floating-Point to Scalar Half-Precision Floating-Point

Converts a scalar single-precision floating-point value to a scalar half-precision floating-point value and writes the converted value to the low-order 16 bits of the destination. When the result is an inexact value, it is rounded as specified by {er} (if specified) or by MXCSR.RC.

There are only extended forms of the instruction:

VCVTSS2SH

The extended form of the instruction has a 128-bit encoding only.

Converts a scalar double-precision floating-point value in the low-order 32 bits of a source XMM register or a 32-bit memory location to a scalar half-precision floating-point value and writes the converted value to the low-order 16 bits of the destination XMM register. For EVEX encodings, the value is written only if the k mask register bit 0 is a '1.' Bits [127:16] of the destination are copied from the first source XMM register. Bits [511:128] of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VCVTSS2USI Convert Scalar Single-Precision Floating-Point to Unsigned Doubleword or Quadword Integer

Converts a single-precision floating-point value to an unsigned integer value and writes the converted value to a general-purpose register.

When the result of the conversion is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum unsigned doubleword (0 to $+2^{32} - 1$) or quadword value (0 to $+2^{64} - 1$), the unsigned indefinite integer value (ffff_ffffh for 32-bit integers, ffff_ffff_ffff_ffffh for 64-bit integers) is returned when the invalid-operation exception (IE) is masked.

There are only extended forms of the instruction:

VCVTSS2USI

The extended form of the instruction has two 128-bit encodings:

- In non 64-bit modes, or in 64-bit mode when EVEX.W = 0, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 32-bit unsigned integer value and writes the converted value to a 32-bit general-purpose register.
- In 64-bit mode when EVEX.W = 1, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 64-bit unsigned integer value and writes the converted value to a 64-bit general-purpose register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Instruction Support

Form	Subset

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTTPD2QQ Convert Packed Double Precision Floating Point to Packed Signed Quadword Integer, Truncated

Converts 2, 4, or 8 packed double precision floating point values to packed signed quadword integer values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is it is truncated (rounded toward zero). When the floating point value is a NaN, infinity, or the result of the conversion is outside the range of an signed quadword (-2^{63} to $+2^{63} - 1$), an invalid-operation exception (IE) is indicated and, if MXCSR.IM masks the IE, the instruction returns the 64-bit indefinite unsigned integer value (8000_0000_0000_0000h).

There are only extended forms of this instruction:

VCVTTPD2QQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts double precision floating point values in a(n) XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to signed quadword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts double precision floating point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to signed quadword integer values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts double precision floating point values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to signed quadword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

VCVTTPH2DQ Convert Packed Half-Precision Floating-Point to Packed Doubleword Integers, Truncated

Converts packed half-precision floating-point values to packed signed doubleword integer values and writes the converted values to the destination.

When the result of the conversion is an inexact value, the value is truncated (rounded toward zero). When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (–231 to +231 – 1), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

There are only extended forms of the instruction:

VCVTTPH2DQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts four packed half-precision floating-point values in an XMM register, a 64-bit memory location or (for EVEX encodings) a broadcast 16-bit memory location to four packed signed doubleword integer values, and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts eight packed half-precision floating-point values in a XMM register, a 128-bit memory location or (for EVEX encodings) a broadcast 16-bit memory location to eight packed signed doubleword integer values, and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts sixteen packed half-precision floating point values in a YMM register, a 256-bit memory location or (for EVEX encodings) a broadcast 16-bit memory location to sixteen packed double-precision floating-point values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VCVTTPH2QQ Convert Packed Half-Precision Floating Point to Packed Quadword Integers, Truncated

Converts four, eight, or sixteen packed half-precision floating point values to packed signed quadword integer values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is truncated (rounded toward zero). When the floating point value is a NaN, infinity, or the result of the conversion is outside the range of a signed quadword (-263 to +263 – 1), an invalid-operation exception (IE) is indicated and, if MXCSR.IM masks the IE, the instruction returns the 64-bit indefinite signed integer value (8000_0000_0000_0000h).

There are only extended forms of this instruction:

VCVTTPH2QQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts half-precision floating point values in a(n) XMM register, a 64-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to signed quadword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts half-precision floating point values in an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to signed quadword integer values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts half-precision floating point values in a MM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to signed quadword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

VCVTTPH2UDQ Convert Packed Half-Precision Floating Point to Packed Unsigned Doubleword Integer, Truncated

Converts eight, sixteen, or thirty-two packed half-precision floating point values to packed unsigned doubleword integer values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is truncated (rounded toward zero). When the floating point value is a NaN, infinity, or the result of the conversion is outside the range of an unsigned doubleword (0 to 232 – 1), an invalid-operation exception (IE) is indicated and, if MXCSR.IM masks the IE, the instruction returns the 32-bit indefinite unsigned integer value (ffff_ffffh).

There are only extended forms of this instruction:

VCVTTPH2UDQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts half-precision floating point values in a(n) XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to unsigned doubleword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts half-precision floating point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to unsigned doubleword integer values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts half-precision floating point values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to unsigned doubleword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VCVTTPH2UW Convert Packed Half-Precision Floating Point to Packed Unsigned Word Integers, Truncated

Converts packed half-precision floating-point values to packed unsigned word integer values and writes the converted values to the destination.

When the result is an inexact value, it is truncated (rounded toward zero). When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed word (0 to $+2^{16}$-1), the instruction returns the 16-bit indefinite unsigned integer value (ffffh) when the invalid-operation exception (IE) is masked.

There are only extended forms of the instruction.

VCVTPH2UW

The extended forms of the instruction have 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts eight half-precision floating-point values in second source XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit unsigned integer values and writes the converted values to the destination XMM register.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts sixteen half-precision floating-point values in second source YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit unsigned integer values and writes the converted values to the destination YMM register.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts thirty-two half-precision floating-point values in second source ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit unsigned integer values and writes the converted values to the destination ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

VCVTTPH2W Convert Packed Half-Precision Floating Point to Packed Signed Word Integers, Truncated

Converts packed half-precision floating-point values to packed signed word integer values and writes the converted values to the destination.

When the result is an inexact value, it is truncated (rounded toward zero). When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed word (- 2^{15} to $+2^{15}$-1), the instruction returns the 16-bit indefinite signed integer value (8000h) when the invalid-operation exception (IE) is masked.

There are only extended forms of the instruction.

VCVTTPH2W

The extended forms of the instruction have 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts eight half-precision floating-point values in the source XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit signed integer values and writes the converted values to the destination XMM register.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts sixteen half-precision floating-point values in second source YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit signed integer values and writes the converted values to the destination YMM register.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts thirty-two half-precision floating-point values in second source ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to 16-bit signed integer values and writes the converted values to the destination ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Converts 2, 4, or 8 packed single precision floating point values to packed unsigned quadword integer values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is truncated (rounded toward zero). When the floating point value is a NaN, infinity, or the result of the conversion is outside the range of an unsigned quadword (0 to $2^{64} - 1$), an invalid-operation exception (IE) is indicated and, if MXCSR.IM masks the IE, the instruction returns the 64-bit indefinite unsigned integer value (ffff_ffff_ffff_ffffh).

There are only extended forms of this instruction:

VCVTTPS2UQQ

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts single precision floating point values in a(n) XMM register, a 64-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to unsigned quadword integer values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts single precision floating point values in an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to unsigned quadword integer values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts single precision floating point values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to unsigned quadword integer values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTTSD2USI Convert Scalar Double-Precision Floating-Point to Unsigned Double- or Quadword Integer, Truncated

Converts a scalar double-precision floating-point value to an unsigned integer value and writes the converted value to a general-purpose register.

When the result of the conversion is an inexact value, the value is truncated (rounded toward zero).

When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum unsigned doubleword (0 to +232 – 1) or quadword value (0 to $+2^{64} – 1$), the instruction returns the unsigned indefinite integer value (ffff_ffffh for 32-bit integers, ffff_ffff_ffff_ffffh for 64-bit integers) when the invalid-operation exception (IE) is masked.

There are only extended forms of the instruction:

VCVTTSD2USI

The extended form of the instruction has two 128-bit encodings:

- In non 64-bit modes, or in 64-bit mode when EVEX.W = 0, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 32-bit unsigned integer and writes the converted value to a 32-bit general purpose register.
- In 64-bit mode when EVEX.W = 1, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 64-bit unsigned integer and writes the converted value to a 64-bit general purpose register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTUDQ2PD Convert Packed Unsigned Doubleword Integer to Packed Double Precision Floating Point

Converts 2, 4, or 8 packed unsigned doubleword integer values to packed double precision floating point values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. The result is always an exact value - no rounding is required, therefore MXCSR.RC and any specified {er} are ignored.

There are only extended forms of this instruction:

VCVTUDQ2PD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts unsigned doubleword integer values in a(n) XMM register, a 64-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to double precision floating point values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts unsigned doubleword integer values in an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to double precision floating point values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts unsigned doubleword integer values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to double precision floating point values and writes the converted values to a ZMM register. Extra line may be added.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression. Note that these EVEX instructions encodings allow for {er} to be specified, even when no rounding is done. It is recommended that {er} not be specified under these circumstances since different assemblers may or may not allow {er} when it is unused.

VCVTUDQ2PH Convert Packed Unsigned Doubleword Integer to Packed Half-Precision Floating Point

Converts four, eight, or sixteen packed unsigned doubleword integer values to packed half-precision floating point values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC.

There are only extended forms of this instruction:

VCVTUDQ2PH

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts unsigned doubleword integer values in a(n) XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location to half-precision floating point values and writes the converted values to an XMM register. Bits [127:64] of the destination and bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts unsigned doubleword integer values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to half-precision floating point values and writes the converted values to an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts unsigned doubleword integer values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to half-precision floating point values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTUQQ2PD Convert Packed Unsigned Quadword Integer to Packed Double Precision Floating Point

Converts 2, 4, or 8 packed unsigned quadword integer values to packed double precision floating point values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC.

There are only extended forms of this instruction:

VCVTUQQ2PD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts unsigned quadword integer values in a(n) XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to double precision floating point values and writes the converted values to an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

Converts unsigned quadword integer values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to double precision floating point values and writes the converted values to a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts unsigned quadword integer values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to double precision floating point values and writes the converted values to a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTUQQ2PH Convert Packed Unsigned Quadword Integer to Packed Half-Precision Floating Point

Converts two, four, or eight packed unsigned quadword integer values to packed half-precision floating point values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC.

There are only extended forms of this instruction:

VCVTUQQ2PH

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts unsigned quadword integer values in an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to half-precision floating point values and writes the converted values to an XMM register. Bits [127:32] of the destination and bits above bit 127 of the corresponding ZMM/YMM register are cleared.

YMM Encoding

Converts unsigned quadword integer values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to half-precision floating point values and writes the converted values to an XMM register. Bits [127:64] of the destination and bits above bit 127 of the ZMM/YMM register corresponding to the destination are cleared.

ZMM Encoding

Converts unsigned quadword integer values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to half-precision floating point values and writes the converted values to an XMM register. Bits above bit 127 of the ZMM/YMM register corresponding to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VCVTUQQ2PS Convert Packed Unsigned Quadword Integer to Packed Double Precision Floating Point

Converts 2, 4, or 8 packed unsigned quadword integer values to packed single precision floating point values and writes the converted values to the destination. Individual elements are written or not based on the value in the K mask register. When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC.

There are only extended forms of this instruction:

VCVTUQQ2PS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts unsigned quadword integer values in a(n) XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to single precision floating point values and writes the converted values to an XMM register. Bits [127:64] of the destination and bits above bit 127 of the corresponding ZMM/YMM register are cleared.

YMM Encoding

Converts unsigned quadword integer values in a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to single precision floating point values and writes the converted values to an XMM register. Bits above bit 127 of the ZMM/YMM register corresponding to the destination are cleared.

ZMM Encoding

Converts unsigned quadword integer values in a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location to single precision floating point values and writes the converted values to a YMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTUSI2SD Convert Unsigned Doubleword or Quadword Integer to Scalar Double-Precision Floating-Point

Converts an unsigned integer value to a double-precision floating-point value and writes the converted value to a destination register.

When the result of the conversion is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC.

There are only extended forms of the instruction:

VCVTUSI2SD

The extended form of the instruction has two 128-bit encodings:

- In non 64-bit modes, or in 64-bit mode when EVEX.W = 0, converts an unsigned doubleword integer value from a 32-bit source general purpose register or a 32-bit memory location to a double-precision floating-point value and writes the converted value to the low-order 64 bits of the destination XMM register. Bits [127:64] of the first source XMM register are copied to the destination XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.
- In 64-bit mode when EVEX.W = 1, converts an unsigned quadword integer value from a 64-bit source general-purpose register or a 64-bit memory location to a double-precision floating-point value and writes the converted value to the low-order 64 bits of the destination XMM register. Bits [127:64] of the first source XMM register are copied to the destination XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression. Note that these EVEX instructions encodings allow for {er} to be specified, even when no rounding is done. It is recommended that {er} not be specified under these circumstances since different assemblers may or may not allow {er} when it is unused.

Instruction Support

[AMD Public Use]

VCVTUSI2SH Convert Unsigned Doubleword or Quadword Integer to Scalar Half-Precision Floating-Point

Converts an unsigned integer value to a half-precision floating-point value and writes the converted value to an XMM register.

When the result of the conversion is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC.

There are only extended forms of the instruction:

VCVTUSI2SH

The extended form of the instruction has two 128-bit encodings:

- In non 64-bit modes, or in 64-bit mode when EVEX.W = 0, converts an unsigned doubleword integer value from a 32-bit source general purpose register or a 32-bit memory location to a half-precision floating-point value and writes the converted value to the low-order 32 bits of the destination XMM register. Bits [127:32] of the first source XMM register are copied to the destination XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.
- In 64-bit mode when EVEX.W = 1, converts an unsigned quadword integer value from a 64-bit source general-purpose register or a 64-bit memory location to a half-precision floating-point value and writes the converted value to the low-order 16 bits of the destination XMM register. Bits [127:16] of the first source XMM register are copied to the destination XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VCVTUW2PH Convert Packed Unsigned Word Integers to Packed Half-Precision Floating-Point

Converts packed unsigned word integer values to packed half-precision floating-point values and writes the converted values to the destination.

When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC.

There are only extended forms of the instruction.

VCVTPH2W

The extended forms of the instruction have 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts eight 16-bit unsigned integer values in the source XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to half-precision floating-point values and writes the converted values to the destination XMM register.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts sixteen 16-bit unsigned integer values in the source YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to half-precision floating-point values and writes the converted values to the destination YMM register.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts thirty-two 16-bit unsigned integer values in the source ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to half-precision floating-point values and writes the converted values to the destination ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

VCVTW2PH Convert Packed Signed Word Integers to Packed Half-Precision Floating-Point

Converts packed signed word integer values to packed half-precision floating-point values and writes the converted values to the destination.

When the result is an inexact value, it is rounded as indicated by {er} (if specified) or by MXCSR.RC.

There are only extended forms of the instruction.

VCVTPH2W

The extended forms of the instruction have 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Converts eight 16-bit signed integer values in the source XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to half-precision floating-point values and writes the converted values to the destination XMM register.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts sixteen 16-bit signed integer values in the source YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to half-precision floating-point values and writes the converted values to the destination YMM register.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Converts thirty-two 16-bit signed integer values in the source ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location to half-precision floating-point values and writes the converted values to the destination ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VDBPSADBW Sum of Absolute Differences of Shuffled and Shifted Bytes

The implementation of this instruction has 2 stages.

In the first stage, each 128-bit block is operated on. The four 32-bits doublewords of the second source operand are shuffled based on the immediate byte into the four 32-bit doublewords of a 128-bit a temporary location. In the second stage 64-bit blocks are operated on. Four different sum of absolute difference operations are performed on 4 unsigned byte lanes with the first source operand and the temporary location shifted. The operation is as follows:

For each 128-bit block:
- Define select_32_bits_from_128(arg1, arg2) as: arg1[31+32*arg2 : 32*arg2]
- TMP[31:0] = select_32_bits_from_128(Src2, imm[1:0])
- TMP[63:32] = select_32_bits_from_128(Src2, imm[3:2])
- TMP[95:64] = select_32_bits_from_128(Src2, imm[5:4])
- TMP[127:96] = select_32_bits_from_128(Src2, imm[7:6])

For each 64-bit block:
- Define sad_of_4_bytes_into_a_word(arg1, arg2) as: |arg1[7:0] – arg2[7:0]| + |arg1[15:8] – arg2[15:8]| + |arg1[23:16] – arg2[23:16]| + |arg1[31:24] – arg2[31:24]|
- DEST[15:0] = sad_of_4_bytes_into_a_word(Src1[31:0], TMP[31:0])
- DEST[31:16] = sad_of_4_bytes_into_a_word(Src1[31:0], TMP[39:8])
- DEST[47:32] = sad_of_4_bytes_into_a_word(Src1[63:32], TMP[47:16])
- DEST[63:48] = sad_of_4_bytes_into_a_word(Src1[63:32], TMP[55:24])

There are only extended forms of the instruction:

VDBPSADBW

The instruction has extended form 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and do not support memory fault suppression.

[AMD Public Use]

VDIVPH Divide Packed Half-Precision Floating-Point

Divides eight, sixteen, or thirty-two packed half-precision floating-point values of the first source operand by the corresponding packed half-precision floating-point value of the second source operand and writes the quotient of each division into the corresponding elements of the destination.

There are only extended forms of the instruction:

VDIVPH

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VEXPANDPD Expand Packed Double-Precision Floating Point Data

Select compressed (contiguous) double-precision floating point elements from the least significant elements of the source operand. The number of elements selected is determined by the number of "1" bits in the K mask register. Expand the selected elements starting at the least significant bit and element, one source element assigned to an element in the destination if the associated mask register bit is "1". Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select and expand elements of the source as mentioned above, and then the original mask value is used to write the destination. When the source operand is memory, the number of "1" bits in the K mask is used to create a new mask to read only the selected elements as one block and memory fault suppression is supported. The mask for the memory read is a compressed version of the K mask, with all of the "1" bits shifted down to the lowest bits. Normal merge masking and zero masking are supported when writing the destination register.

For example, when expanding up to 8 double-precision floating point data elements from a ZMM register or memory, if the K mask register is binary 10010010, the mask bits are "1" for elements 7, 4, and 1. Since there are 3 "1" bits in the mask value, 3 elements are read from the source operand (register or memory). These elements are then expanded, or distributed, into elements 1, 4, and 7 of the destination using the K mask (of course, none of these elements are masked off since their mask bits are all "1"). The other elements of the destination all have a "0" K mask bit and are merge-masked or zero masked according to the EVEX.z bit as usual.

The VCOMPRESSPD/PS instruction is effectively the opposite of the VEXPANDPD/PS instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction read from memory based on the compressed k mask per 64-bit element as described above and support memory fault suppression based on the compressed k mask.

VEXPANDPS Expand Packed Single Precision Floating Point Data

Select compressed (contiguous) single precision floating point elements from the least significant elements of the source operand. The number of elements selected is determined by the number of "1" bits in the K mask register. Expand the selected elements starting at the least significant bit and element, one source element assigned to an element in the destination if the associated mask register bit is "1". Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select and expand elements of the source as mentioned above, and then the original mask value is used to write the destination. When the source operand is memory, the number of "1" bits in the K mask is used to create a new k mask to read only the selected elements as one block and memory fault suppression is supported. The new mask for the memory read is a compressed version of the K mask, with all of the "1" bits shifted down to the lowest bits. Normal merge masking and zero masking are supported when writing the destination register.

See the VEXPANDPD instruction for an example of how the VEXPANDxx instructions work. The VCOMPRESSPD/PS instruction is effectively the opposite of the VEXPANDPD/PS instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings.

XMM Encoding

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction read from memory based on the compressed k mask per 32-bit element as described above and support memory fault suppression based on the compression k mask.

VEXTRACTF128 Extract Packed Floating-Point Values

Extracts 128 bits of packed data from a YMM register as specified by an immediate byte operand, and writes it to either an XMM register or a 128-bit memory location.

Only bit [0] of the immediate operand is used. Operation is as follows.

- When imm8[0] = 0, copy bits [127:0] of the source to the destination.
- When imm8[0] = 1, copy bits [255:128] of the source to the destination.

This extended-form instruction has a single 256-bit encoding:

The source operand is a YMM register and the destination is an XMM register or a 128-bit memory location. There is a third immediate byte operand.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VEXTRACTF64X2 Extract 2 Double Precision Floating Point Values

Copies 128 bits (2 double precision floating point values) from the source operand as specified by the immediate byte. Immediate Byte bit [0] is used to determine which half of a 256-bit source to copy. Immediate Byte bits [1:0] are used to determine which quarter of a 512-bit source to copy. Higher bits in the immediate byte are ignored.

There are only extended forms of the instruction:

VEXTRACTF64X2

The extended form of the instruction has 256-bit and 512-bit encodings:

YMM Encoding

The source operand is a YMM register. The destination is an XMM register or a 128-bit memory location. When the destination is an XMM register, bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register. The destination is an XMM register or a 128-bit memory location. When the destination is an XMM register, bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

Instruction Support

Form	Subset
EVEX VEXTRACTF64X2 256-bit	AVX512VL, AVX512DQ
EVEX VEXTRACTF64X2 512-bit	AVX512DQ

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VEXTRACTI128 Extract 128-bit Integer

Writes a selected 128-bit half of a YMM register to an XMM register or a 128-bit memory location based on the value of bit 0 of an immediate byte.

There is a single form of this instruction:

VEXTRACTI128 *dest, src, imm8*

If imm8[0] = 0, the lower half of the source YMM register is selected; if imm8[0] = 1, the upper half of the source register is selected.

There is a single VEX.L = 1 encoding of this instruction.

The source operand is a YMM register. The destination is an XMM register or a 128-bit memory location. When the destination is a register, Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

VFCMADDCPH Complex Conjugate Fused Multiply-Add on Packed Half-Precision Data

Perform a complex conjugate fused multiply-add operation on each complex number in the data.

Each complex number consists of an even/odd pair of half-precision floating point values. The even of the pair is the real portion of the complex number. The odd of the pair is the inaginary portion of the complex number.

The operation performed is (where .r indicates the real portion and .i indicates the imaginary portion of the complex number):

```
dest.r = dest.r + src1.r * src2.r + src1.i * src2.i
dest.i = dest.i + src1.i * src2.r - src1.r * src2.i
```

The operation is done in two operations. The first operation is a fused-multiply-add performing the first multiplies in the above equations, adding it to the existing destination value. The second operation is a fused-multiply-add performing the second multiplies in the above equation and adding/subtracting it to/from the result of the first operation. This has implications, some of which include:

- The result of the first operation will be rounded before being input into the second operation.
- An overflow generated by the first operation cannot be brought back in range by the second operation.
- A Denorm generated by the first operation, input into the second operation will cause MXCSR.DE to be set.

There are only extended forms of this instruction:

VFCMADDCPH

The extended form of the instruction has 128-bit, 256-bit and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register corresponding to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register corresponding to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is either a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

VFCMULCSH Complex Conjugate Multiply on Scalar Half-Precision Data

Perform a complex conjugate multiply operation on the low complex number in the data. Each complex number consists of an even/odd pair of half-precision floating point values. The even of the pair is the real portion of the complex number. The odd of the pair is the inaginary portion of the complex number.

The operation performed is (where .r indicates the real portion and .i indicates the imaginary portion of the complex number):

```
dest.r = src1.r * src2.r + src1.i * src2.i
dest.i = src1.i * src2.r - src1.r * src2.i
```

The operation is done in two operations. The first operation is a multiply performing the first multiplies in the above equations. The second operation is a fused-multiply-add performing the second multiplies in the above equation and adding/subtracting it to/from the result of the first operation.

This has implications, some of which include:

- The result of the first operation will be rounded before being input into the second operation.
- An overflow generated by the first operation cannot be brought back in range by the second operation.
- A Denorm generated by the first operation, input into the second operation will cause MXCSR.DE to be set.

There are only extended forms of this instruction:

VFCMULCSH

The extended form of the instruction has 128-bit, 256-bit and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register, a 32-bit memory location. The destination is a third XMM register. Bits [127:32] of the first source operand are copied to bits [127:32] of the destination. Bits above bit 127 of the YMM/ZMM register corresponding to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register, a 32-bit memory location. The destination is a third YMM register. Bits [127:32] of the first source operand are copied to bits [127:32] of the destination. Bits above bit 255 of the ZMM register corresponding to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is either a ZMM register, a 32-bit memory location. The destination is a third ZMM register. Bits [127:32] of the first source operand are copied to bits [127:32] of the destination.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

In addition, #UD will be generated if the destination register is the same as either source register.

[AMD Public Use]

VFIXUPIMMPD Fix-Up Packed Double Precision Floating Point Values

Generate fix-up values for various special cases of input double precision floating point data based on the type of date.

The instruction first processes MXCSR.DAZ on each input element in the first source operand. Each element of the data is then classified into one of the following 8 classifications:

Input Value	Classification Value ‘c’
QNaN	0
SNaN	1
Zero	2
+1.0	3
-Infinity	4
+Infinity	5
Negative Value	6
Positive Value	7

Note that these classifications are mutually exclusive except for the value +1.0, which will classify with value 3. All input values will fall into one of these classifications.

The classification value (‘c’, values 0-7) is then used to look up 4 bits in a 32-bit lookup table contained in the second source operand element. The bits looked up are [3+4*c:4*c]. These bits are then decoded to determine how to generate the output element:

Lookup Table Bits	Output Element
0000b	dest (destination remains unchanged)
0001b	src1 element after DAZ processing
0010b	QNaN based on src1 element after DAZ processing
0011b	QNaN Indefinite
0100b	-Inf
0101b	+Inf
0110b	Infinity with sign of src1 element after DAZ processing
0111b	-0
1000b	+0
1001b	-1
1010b	+1
1011b	+1/2
1100b	90.0

[AMD Public Use]

Lookup Table Bits	Output Element
1101b	Pi/2
1110b	Maximum Float Value
1111b	-Maximum Float Value

Floating point exception reporting is then processed based on the immediate value bits. Multiple floating-point exceptions may be reported.

Immediate Bit	Exception
0	ZE if c == 2 // Zero value
1	IE if c == 2 // Zero value
2	ZE if c == 3// One value
3	IE if c == 3// One value
4	IE if c == 1// SNaN value
5	IE if c == 4// -Inf value
6	IE if c == 6// Negative value
7	IE if c == 5// +Inf value

VFIXUPIMMPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

VFMADDCPH Complex Fused Multiply-add on Packed Half-Precision Data

Perform a complex fused multiply-add operation on each complex number in the data. Each complex number consists of an even/odd pair of half-precision floating point values. The even of the pair is the real portion of the complex number. The odd of the pair is the inaginary portion of the complex number.

The operation performed is (where .r indicates the real portion and .i indicates the imaginary portion of the complex number):

```
dest.r = dest.r + src1.r * src2.r - src1.i * src2.i
dest.i = dest.i + src1.i * src2.r + src1.r * src2.i
```

The operation is done in two operations. The first operation is a fused-multiply-add performing the first multiplies in the above equations, adding it to the existing destination value. The second operation is a fused-multiply-add performing the second multiplies in the above equation and adding/subtracting it to/from the result of the first operation. This has implications, some of which include:

- The result of the first operation will be rounded before being input into the second operation.
- An overflow generated by the first operation cannot be brought back in range by the second operation.
- A Denorm generated by the first operation, input into the second operation will cause MXCSR.DE to be set.

There are only extended forms of this instruction:

VFMADDCPH

The extended form of the instruction has 128-bit, 256-bit and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register corresponding to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register corresponding to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is either a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

VFMADDPD VFMADD132PD VFMADD213PD VFMADD231PD — Multiply and Add Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors and adds the unrounded product to a third double-precision floating-point vector producing a precise result which is then rounded to double-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding). The rounded sum is written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFMADDPD dest, src1, src2/mem, src3      // dest = (src1* src2/mem) + src3
VFMADDPD dest, src1, src2, src3/mem      // dest = (src1* src2) + src3/mem
```

and three three-operand forms:

```
VFMADD132PD src1, src2, src3/mem         // src1 = (src1* src3/mem) + src2
VFMADD213PD src1, src2, src3/mem         // src1 = (src2* src1) + src3/mem
VFMADD231PD src1, src2, src3/mem         // src1 = (src2* src3/mem) + src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two double-precision elements per vector) and register-based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four double-precision elements per vector) and register-based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight double-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

When VEX.W = 0, the second source is a register or a memory location and the third source is a register.

- When VEX.W = 1, the second source is a register, and the third source is a register or a memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 64-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by VEX.L or EVEX.L'L. When the destination is an XMM register (L = 0 or L'L == 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L = 1 or L'L == 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Exceptions

Exception	Mode			Cause of Exception
	Real	Virt	Prot	
Invalid opcode, #UD			F	Instruction not supported, as indicated by CPUID feature identifier.
	F	F		FMA instructions are only recognized in protected mode.
			F	CR4.OSXSAVE = 0, indicated by CPUID Fn0000_0001_ECX[OSXSAVE].
			F	XFEATURE_ENABLED_MASK[2:1] ! = 11b.
			F	REX, F2, F3, or 66 prefix preceding VEX prefix.
			F	Lock prefix (F0h) preceding opcode.
			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 0, see *SIMD Floating-Point Exceptions* below for details.
Device not available, #NM			F	CR0.TS = 1.
Stack, #SS			F	Memory address exceeding stack segment limit or non-canonical.
General protection, #GP			F	Memory address exceeding data segment limit or non-canonical.
			F	Null data segment used to reference memory.
Page fault, #PF			F	Instruction execution caused a page fault.
Alignment check, #AC			F	Memory operand not 16-byte aligned when alignment checking enabled.
SIMD floating-point, #XF			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid operation, IE			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VFMADD132PH VFMADD213PH VFMADD231PH — Multiply and Add Packed Half-Precision Floating-Point

Multiplies together two half-precision floating-point vectors and adds the unrounded product to a third half-precision floating-point vector producing a precise result which is then rounded to half-precision based on the mode specified by {er} (if specified) or by MXCSR.RC. The rounded sum is written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are three three-operand forms:

```
VFMADD132PH src1, src2, src3/mem    // src1 = (src1* src3/mem) + src2
VFMADD213PH src1, src2, src3/mem    // src1 = (src2* src1) + src3/mem
VFMADD231PH src1, src2, src3/mem    // src1 = (src2* src3/mem) + src1
```

When EVEX.L'L = 00b, the vector size is 128 bits (eight half-precision elements per vector) and register-based source operands are held in XMM registers.

When EVEX.L'L = 01b, the vector size is 256 bits (sixteen half-precision elements per vector) and register-based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (thirty-two half-precision elements per vector) and register based source operands are held in ZMM registers.

The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 16-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by EVEX.L'L. When the destination is an XMM register (L'L = 00b), bits [512:128] of the corresponding

YMM/ZMM register are cleared. When the destination is a YMM register (L'L = 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions”.

[AMD Public Use]

VFMADD132SH VFMADD213SH VFMADD231SH — Multiply and Add Scalar Half-Precision Floating-Point

Multiplies together two half-precision floating-point values and adds the unrounded product to a third half-precision floating-point value producing a precise result which is then rounded to half-precision based on the mode specified by {er} (if specified) or by MXCSR.RC.. The rounded sum is written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are three three-operand forms:

```
VFMADD132SH src1, src2, src3/mem32      // src1 = (src1* src3/mem32) + src2
VFMADD213SH src1, src2, src3/mem32      // src1 = (src2* src1) + src3/mem32
VFMADD231SH src1, src2, src3/mem32      // src1 = (src2* src3/mem32) + src1
```

When EVEX.L'L = 00b, the vector size is 128 bits (two half-precision elements per vector) and register based source operands are held in XMM registers.

When EVEX.L'L = 01b, the vector size is 256 bits (four half-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight half-precision elements per vector) and register based source operands are held in ZMM registers.

All 16-bit half-precision floating-point register-based operands are held in the lower word of XMM registers. The result is written to the low word of the destination register. For those instructions that use a memory-based operand, one of the source operands is a 16-bit value read from memory.

The first and second operands are registers and the third operand is a register, 32-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:32] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions”.

[AMD Public Use]

VFMADDPS VFMADD132PS VFMADD213PS VFMADD231PS — Multiply and Add Packed Single-Precision Floating-Point

Multiplies together two single-precision floating-point vectors and adds the unrounded product to a third single-precision floating-point vector producing a precise result which is then rounded to single-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding). The rounded sum is written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFMADDPS dest, src1, src2/mem, src3      // dest = (src1* src2/mem) + src3
VFMADDPS dest, src1, src2, src3/mem      // dest = (src1* src2) + src3/mem
```

and three three-operand forms:

```
VFMADD132PS src1, src2, src3/mem         // src1 = (src1* src3/mem) + src2
VFMADD213PS src1, src2, src3/mem         // src1 = (src2* src1) + src3/mem
VFMADD231PS src1, src2, src3/mem         // src1 = (src2* src3/mem) + src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (four single-precision elements per vector) and register-based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (eight single-precision elements per vector) and register-based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (sixteen single-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

When VEX.W = 0, the second source is a register or a memory location and the third source is a register.

- When VEX.W = 1, the second source is a register, and the third source is a register or a memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by VEX.L or EVEX.L'L. When the destination is an XMM register (L = 0 or L'L == 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L = 1 or L'L == 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

Page fault, #PF			F	Instruction execution caused a page fault.
Alignment check, #AC			F	Memory operand not 16-byte aligned when alignment checking enabled.
SIMD floating-point, #XF			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid operation, IE			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VFMADDSD VFMADD132SD VFMADD213SD VFMADD231SD — Multiply and Add Scalar Double-Precision Floating-Point

Multiplies together two double-precision floating-point values and adds the unrounded product to a third double-precision floating-point value producing a precise result which is then rounded to double-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding). The rounded sum is written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

```
VFMADDSD dest, src1, src2/mem64, src3      // dest = (src1* src2/mem64) + src3
VFMADDSD dest, src1, src2, src3/mem64      // dest = (src1* src2) + src3/mem64
```

and three three-operand forms:

```
VFMADD132SD src1, src2, src3/mem64         // src1 = (src1* src3/mem64) + src2
VFMADD213SD src1, src2, src3/mem64         // src1 = (src2* src1) + src3/mem64
VFMADD231SD src1, src2, src3/mem64         // src1 = (src2* src3/mem64) + src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two double-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four double-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight double-precision elements per vector) and register based source operands are held in ZMM registers

All 64-bit double-precision floating-point register-based operands are held in the lower quadword of XMM registers. The result is written to the lower quadword of the destination register. For those instructions that use a memory-based operand, one of the source operands is a 64-bit value read from memory.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a 64-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a 64-bit memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a 64-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:64] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

[AMD Public Use]

VFMADDSS VFMADD132SS VFMADD213SS VFMADD231SS — Multiply and Add Scalar Single-Precision Floating-Point

Multiplies together two single-precision floating-point values and adds the unrounded product to a third single-precision floating-point value producing a precise result which is then rounded to single-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding). The rounded sum is written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

```
VFMADDSS dest, src1, src2/mem32, src3      // dest = (src1* src2/mem32) + src3
VFMADDSS dest, src1, src2, src3/mem32      // dest = (src1* src2) + src3/mem32
```

and three three-operand forms:

```
VFMADD132SS src1, src2, src3/mem32         // src1 = (src1* src3/mem32) + src2
VFMADD213SS src1, src2, src3/mem32         // src1 = (src2* src1) + src3/mem32
VFMADD231SS src1, src2, src3/mem32         // src1 = (src2* src3/mem32) + src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two single-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four single-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight single-precision elements per vector) and register based source operands are held in ZMM registers.

All 32-bit single-precision floating-point register-based operands are held in the lower doubleword of XMM registers. The result is written to the low doubleword of the destination register. For those instructions that use a memory-based operand, one of the source operands is a 32-bit value read from memory.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a 32-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a 32-bit memory location.

For the three-operand forms, (E)VEX.W is 0. The first and second operands are registers and the third operand is a register, 32-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:32] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

[AMD Public Use]

VFMADDSUB132PH VFMADDSUB213PH VFMADDSUB231PH — Multiply with Alternating Add/Subtract Packed Half-Precision Floating-Point

Multiplies together two half-precision floating-point vectors, adds odd elements of the unrounded product to odd elements of a third half-precision floating-point vector, and subtracts even elements of the third floating point vector from even elements of unrounded product. The precise result of each addition or subtraction is then rounded to half-precision based on the mode specified by {er} (if specified) or by MXCSR.RC, and written to the corresponding element of the destination.

The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are three three-operand forms:

VFMADDSUB132PH *src1, src2, src3/mem*	// $src1_{odd}$ = ($src1_{odd}$ * $src3_{odd}$ /mem_{odd}) + $src2_{odd}$
	// $src1_{even}$ = ($src1_{even}$ * $src3_{even}$ /mem_{even}) − $src2_{even}$
VFMADDSUB213PH *src1, src2, src3/mem*	// $src1_{odd}$ = ($src2_{odd}$ * $src1_{odd}$) + $src3_{odd}$/mem_{odd}
	// $src1_{even}$ = ($src2_{even}$ * $src1_{even}$) − $src3_{even}$/mem_{even}
VFMADDSUB231PH *src1, src2, src3/mem*	// $src1_{odd}$ = ($src2_{odd}$ * $src3_{odd}$/mem_{odd}) + $src1_{odd}$
	// $src1_{even}$ = ($src2_{even}$ * $src3_{even}$/mem_{even}) − $src1_{even}$

When EVEX.L'L = 00b, the vector size is 128 bits (eight half-precision elements per vector) and register based source operands are held in XMM registers.

When EVEX.L'L = 01b, the vector size is 256 bits (sixteen half-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (thirty-two half-precision elements per vector) and register based source operands are held in ZMM registers.

The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 16-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by EVEX.L'L. When the destination is an XMM register (L'L = 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L'L = 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Instruction Support

Form	Subset
VFMADDSUB*nnn*PH 128, 256	AVX512VL AVX512_FP16
VFMADDSUB*nnn*PH 512	AVX512_FP16

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions”.

[AMD Public Use]

VFMADDSUBPD VFMADDSUB132PD VFMADDSUB213PD VFMADDSUB231PD — Multiply with Alternating Add/Subtract Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors, adds odd elements of the unrounded product to odd elements of a third double-precision floating-point vector, and subtracts even elements of the third floating point vector from even elements of unrounded product. The precise result of each addition or subtraction is then rounded to double-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the corresponding element of the destination.

The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

VFMADDSUBPD *dest, src1, src2/mem, src3*	// $dest_{odd} = (src1_{odd} * src2_{odd}/mem_{odd}) + src3_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}/mem_{even}) - src3_{even}$
VFMADDSUBPD *dest, src1, src2, src3/mem*	// $dest_{odd} = (src1_{odd} * src2_{odd}) + src3_{odd}/mem_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}) - src3_{even}/mem_{even}$

and three three-operand forms:

VFMADDSUB132PD *src1, src2, src3/mem*	// $src1_{odd} = (src1_{odd} * src3_{odd}/mem_{odd}) + src2_{odd}$ // $src1_{even} = (src1_{even} * src3_{even}/mem_{even}) - src2_{even}$
VFMADDSUB213PD *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src1_{odd}) + src3_{odd}/mem_{odd}$ // $src1_{even} = (src2_{even} * src1_{even}) - src3_{even}/mem_{even}$
VFMADDSUB231PD *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src3_{odd}/mem_{odd}) + src1_{odd}$ // $src1_{even} = (src2_{even} * src3_{even}/mem_{even}) - src1_{even}$

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two double-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four double-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight double-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, or a memory location, or (for EVEX encodings) a broadcast 64-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by VEX.L or EVEX.L'L. When the destination is an XMM register (L = 0 or L'L == 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L = 1 or L'L == 01b), bits [512:255] of the corresponding ZMM register are cleared.

[AMD Public Use]

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Exception	Mode			Cause of Exception
	Real	Virt	Prot	
Invalid opcode, #UD			F	Instruction not supported, as indicated by CPUID feature identifier.
	F	F		FMA instructions are only recognized in protected mode.
			F	CR4.OSXSAVE = 0, indicated by CPUID Fn0000_0001_ECX[OSXSAVE].
			F	XFEATURE_ENABLED_MASK[2:1] ! = 11b.
			F	REX, F2, F3, or 66 prefix preceding VEX prefix.
			F	Lock prefix (F0h) preceding opcode.
			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 0, see *SIMD Floating-Point Exceptions* below for details.
Device not available, #NM			F	CR0.TS = 1.
Stack, #SS			F	Memory address exceeding stack segment limit or non-canonical.
General protection, #GP			F	Memory address exceeding data segment limit or non-canonical.
			F	Null data segment used to reference memory.
Page fault, #PF			F	Instruction execution caused a page fault.
Alignment check, #AC			F	Memory operand not 16-byte aligned when alignment checking enabled.
SIMD floating-point, #XF			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid operation, IE			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VFMADDSUBPS VFMADDSUB132PS VFMADDSUB213PS VFMADDSUB231PS — Multiply with Alternating Add/Subtract Packed Single-Precision Floating-Point

Multiplies together two single-precision floating-point vectors, adds odd elements of the unrounded product to odd elements of a third single-precision floating-point vector, and subtracts even elements of the third floating point vector from even elements of unrounded product. The precise result of each addition or subtraction is then rounded to single-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the corresponding element of the destination.

The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

VFMADDSUBPS *dest, src1, src2/mem, src3*	// $dest_{odd} = (src1_{odd} * src2_{odd}/mem_{odd}) + src3_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}/mem_{even}) - src3_{even}$
VFMADDSUBPS *dest, src1, src2, src3/mem*	// $dest_{odd} = (src1_{odd} * src2_{odd}) + src3_{odd}/mem_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}) - src3_{even}/mem_{even}$

and three three-operand forms:

VFMADDSUB132PS *src1, src2, src3/mem*	// $src1_{odd} = (src1_{odd} * src3_{odd}/mem_{odd}) + src2_{odd}$ // $src1_{even} = (src1_{even} * src3_{even}/mem_{even}) - src2_{even}$
VFMADDSUB213PS *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src1_{odd}) + src3_{odd}/mem_{odd}$ // $src1_{even} = (src2_{even} * src1_{even}) - src3_{even}/mem_{even}$
VFMADDSUB231PS *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src3_{odd}/mem_{odd}) + src1_{odd}$ // $src1_{even} = (src2_{even} * src3_{even}/mem_{even}) - src1_{even}$

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two single-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four single-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight single-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by VEX.L or EVEX.L'L. When the destination is an XMM register (L = 0 or L'L == 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L = 1 or L'L == 01b), bits [512:255] of the corresponding ZMM register are cleared.

[AMD Public Use]

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

VFMSUBADDPD VFMSUBADD132PD VFMSUBADD213PD VFMSUBADD231PD — Multiply with Alternating Subtract/Add Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors, adds even elements of the unrounded product to even elements of a third double-precision floating-point vector, and subtracts odd elements of the third floating point vector from odd elements of unrounded product. The precise result of each addition or subtraction is then rounded to double-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the corresponding element of the destination.

The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

VFMSUBADDPD *dest, src1, src2/mem, src3*	// $dest_{odd} = (src1_{odd} * src2_{odd}/mem_{odd}) - src3_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}/mem_{even}) + src3_{even}$
VFMSUBADDPD *dest, src1, src2, src3/mem*	// $dest_{odd} = (src1_{odd} * src2_{odd}) - src3_{odd}/mem_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}) + src3_{even}/mem_{even}$

and three three-operand forms:

VFMSUBADD132PD *src1, src2, src3/mem*	// $src1_{odd} = (src1_{odd} * src3_{odd}/mem_{odd}) - src2_{odd}$ // $src1_{even} = (src1_{even} * src3_{even}/mem_{even}) + src2_{even}$
VFMSUBADD213PD *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src1_{odd}) - src3_{odd}/mem_{odd}$ // $src1_{even} = (src2_{even} * src1_{even}) + src3_{even}/mem_{even}$
VFMSUBADD231PD *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src3_{odd}/mem_{odd}) - src1_{odd}$ // $src1_{even} = (src2_{even} * src3_{even}/mem_{even}) + src1_{even}$

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two double-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four double-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight double-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source operand is a register or a memory location.

The first and second operands are registers and the third operand is a register, or a memory location, or (for EVEX encodings) a broadcast 64-bit location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by VEX.L or EVEX.L'L. When the destination is an XMM register (L = 0 or L'L == 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L = 1 or L'L == 01b), bits [512:255] of the corresponding ZMM register are cleared.

[AMD Public Use]

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

	Real	Virt	Prot	
Invalid opcode, #UD			F	Instruction not supported, as indicated by CPUID feature identifier.
	F	F		FMA instructions are only recognized in protected mode.
			F	CR4.OSXSAVE = 0, indicated by CPUID Fn0000_0001_ECX[OSXSAVE].
			F	XFEATURE_ENABLED_MASK[2:1] ! = 11b.
			F	REX, F2, F3, or 66 prefix preceding VEX prefix.
			F	Lock prefix (F0h) preceding opcode.
			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 0, see *SIMD Floating-Point Exceptions* below for details.
Device not available, #NM			F	CR0.TS = 1.
Stack, #SS			F	Memory address exceeding stack segment limit or non-canonical.
General protection, #GP			F	Memory address exceeding data segment limit or non-canonical.
			F	Null data segment used to reference memory.
Page fault, #PF			F	Instruction execution caused a page fault.
Alignment check, #AC			F	Memory operand not 16-byte aligned when alignment checking enabled.
SIMD floating-point, #XF			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid operation, IE			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VFMSUBADDPS VFMSUBADD132PS VFMSUBADD213PS VFMSUBADD231PS — Multiply with Alternating Subtract/Add Packed Single-Precision Floating-Point

Multiplies together two single-precision floating-point vectors, adds even elements of the unrounded product to even elements of a third single-precision floating-point vector, and subtracts odd elements of the third floating point vector from odd elements of unrounded product. The precise result of each addition or subtraction is then rounded to single-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the corresponding element of the destination.

The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

VFMSUBADDPS *dest, src1, src2/mem, src3*	// $dest_{odd} = (src1_{odd} * src2_{odd}/mem_{odd}) - src3_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}/mem_{even}) + src3_{even}$
VFMSUBADDPS *dest, src1, src2, src3/mem*	// $dest_{odd} = (src1_{odd} * src2_{odd}) - src3_{odd}/mem_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}) + src3_{even}/mem_{even}$

and three three-operand forms:

VFMSUBADD132PS *src1, src2, src3/mem*	// $src1_{odd} = (src1_{odd} * src3_{odd}/mem_{odd}) - src2_{odd}$ // $src1_{even} = (src1_{even} * src3_{even}/mem_{even}) + src2_{even}$
VFMSUBADD213PS *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src1_{odd}) - src3_{odd}/mem_{odd}$ // $src1_{even} = (src2_{even} * src1_{even}) + src3_{even}/mem_{even}$
VFMSUBADD231PS *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src3_{odd}/mem_{odd}) - src1_{odd}$ // $src1_{even} = (src2_{even} * src3_{even}/mem_{even}) + src1_{even}$

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two single-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four single-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight single-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, or a memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by VEX.L or EVEX.L'L. When the destination is an XMM register (L = 0 or L'L == 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L = 1 or L'L == 01b), bits [512:255] of the corresponding ZMM register are cleared.

[AMD Public Use]

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VFMSUBPD VFMSUB132PD VFMSUB213PD VFMSUB231PD — Multiply and Subtract Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors and subtracts a third double-precision floating-point vector from the unrounded product to produce a precise intermediate result. The intermediate result is then rounded to double-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFMSUBPD dest, src1, src2/mem, src3      // dest = (src1* src2/mem) − src3
VFMSUBPD dest, src1, src2, src3/mem      // dest = (src1* src2) − src3/mem
```

and three three-operand forms:

```
VFMSUB132PD src1, src2, src3/mem         // src1 = (src1* src3/mem) − src2
VFMSUB213PD src1, src2, src3/mem         // src1 = (src2* src1) − src3/mem
VFMSUB231PD src1, src2, src3/mem         // src1 = (src2* src3/mem) − src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two double-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four double-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight double-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a memory location.

For the three-operand forms, VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location or (for EVEX encodings) a broadcast 64-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by VEX.L or EVEX.L'L. When the destination is an XMM register (L = 0 or L'L == 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L = 1 or L'L == 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

VFMSUB132PH VFMSUB213PH VFMSUB231PH — Multiply and Subtract Packed Half-Precision Floating-Point

Multiplies together two half-precision floating-point vectors and subtracts a third half-precision floating-point vector from the unrounded product to produce a precise intermediate result. The intermediate result is then rounded to half-precision based on the mode specified by {er} (if specified) or by MXCSR.RC, and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are three three-operand forms:

```
VFMSUB132PH src1, src2, src3/mem    // src1 = (src1* src3/mem) − src2
VFMSUB213PH src1, src2, src3/mem    // src1 = (src2* src1) − src3/mem
VFMSUB231PH src1, src2, src3/mem    // src1 = (src2* src3/mem) − src1
```

When EVEX.L'L = 00b, the vector size is 128 bits (eight half-precision elements per vector) and register based source operands are held in XMM registers.

When EVEX.L'L = 01b, the vector size is 256 bits (sixteen half-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (thirty-two half-precision elements per vector) and register based source operands are held in ZMM registers

The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 16-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by EVEX.L'L. When the destination is an XMM register (L'L = 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L'L = 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions”.

[AMD Public Use]

VFMSUBPS VFMSUB132PS VFMSUB213PS VFMSUB231PS — Multiply and Subtract Packed Single-Precision Floating-Point

Multiplies together two single-precision floating-point vectors and subtracts a third single-precision floating-point vector from the unrounded product to produce a precise intermediate result. The intermediate result is then rounded to single-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFMSUBPS dest, src1, src2/mem, src3      // dest = (src1* src2/mem) − src3
VFMSUBPS dest, src1, src2, src3/mem      // dest = (src1* src2) − src3/mem
```

and three three-operand forms:

```
VFMSUB132PS src1, src2, src3/mem         // src1 = (src1* src3/mem) − src2
VFMSUB213PS src1, src2, src3/mem         // src1 = (src2* src1) − src3/mem
VFMSUB231PS src1, src2, src3/mem         // src1 = (src2* src3/mem) − src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (four single-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (eight single-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (sixteen single-precision elements per vector) and register based source operands are held in ZMM registers

- When VEX.W = 0, the second source is a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The destination is an XMM register or, a YMM register or a ZMM register, as determined by VEX.L or EVEX.L'L. When the destination is an XMM register (L = 0 or L'L == 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L = 1 or L'L == 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

			F	XFEATURE_ENABLED_MASK[2:1] ! = 11b.
			F	REX, F2, F3, or 66 prefix preceding VEX prefix.
			F	Lock prefix (F0h) preceding opcode.
			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 0, see *SIMD Floating-Point Exceptions* below for details.
Device not available, #NM			F	CR0.TS = 1.
Stack, #SS			F	Memory address exceeding stack segment limit or non-canonical.
General protection, #GP			F	Memory address exceeding data segment limit or non-canonical.
			F	Null data segment used to reference memory.
Page fault, #PF			F	Instruction execution caused a page fault.
Alignment check, #AC			F	Memory operand not 16-byte aligned when alignment checking enabled.
SIMD floating-point, #XF			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid operation, IE			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VFMSUBSD VFMSUB132SD VFMSUB213SD VFMSUB231SD — Multiply and Subtract Scalar Double-Precision Floating-Point

Multiplies together two double-precision floating-point values and subtracts a third double-precision floating-point value from the unrounded product to produce a precise intermediate result. The intermediate result is then rounded to double-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFMSUBSD dest, src1, src2/mem, src3     // dest = (src1* src2/mem) − src3
VFMSUBSD dest, src1, src2, src3/mem     // dest = (src1* src2) − src3/mem
```

and three three-operand forms:

```
VFMSUB132SD src1, src2, src3/mem        // src1 = (src1* src3/mem) − src2
VFMSUB213SD src1, src2, src3/mem        // src1 = (src2* src1) − src3/mem
VFMSUB231SD src1, src2, src3/mem        // src1 = (src2* src3/mem) − src1
```

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two double-precision elements per vector) and register based source operands are held in XMM registers.
- When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four double-precision elements per vector) and register based source operands are held in YMM registers.
- When EVEX.L'L = 10b, the vector size is 512 bits (eight double-precision elements per vector) and register based source operands are held in ZMM registers.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 64-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:64] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Instruction Support

Form	Subset

VFMSUB132SH VFMSUB213SH VFMSUB231SH — Multiply and Subtract Scalar Half-Precision Floating-Point

Multiplies together two half-precision floating-point values and subtracts a third half-precision floating-point value from the unrounded product to produce a precise intermediate result. The intermediate result is then rounded to half-precision based on the mode specified by {er} (if specified) or by MXCSR.RC, [and remove extra period here] and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are three three-operand forms:

```
VFMSUB132SH src1, src2, src3/mem    // src1 = (src1* src3/mem) − src2
VFMSUB213SH src1, src2, src3/mem    // src1 = (src2* src1) − src3/mem
VFMSUB231SH src1, src2, src3/mem    // src1 = (src2* src3/mem) − src1
```

The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 16-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:16] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions”.

[AMD Public Use]

VFMSUBADD132PH VFMSUBADD213PH VFMSUBADD231PH — Multiply with Alternating Subtract/Add Packed Half-Precision Floating-Point

Multiplies together two half-precision floating-point vectors, adds even elements of the unrounded product to even elements of a third half-precision floating-point vector, and subtracts odd elements of the third floating point vector from odd elements of unrounded product. The precise result of each addition or subtraction is then rounded to half-precision based on the mode specified {er} (if specified) or by MXCSR.RC, and written to the corresponding element of the destination.

The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are three three-operand forms:

VFMSUBADD132PH *src1, src2, src3/mem*	// $src1_{odd} = (src1_{odd} * src3_{odd} / mem_{odd}) - src2_{odd}$ // $src1_{even} = (src1_{even} * src3_{even} / mem_{even}) + src2_{even}$
VFMSUBADD213PH *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src1_{odd}) - src3_{odd} / mem_{odd}$ // $src1_{even} = (src2_{even} * src1_{even}) + src3_{even} / mem_{even}$
VFMSUBADD231PH *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src3_{odd} / mem_{odd}) - src1_{odd}$ // $src1_{even} = (src2_{even} * src3_{even} / mem_{even}) + src1_{even}$

When EVEX.L'L = 00b, the vector size is 128 bits (eight half-precision elements per vector) and register based source operands are held in XMM registers.

When EVEX.L'L = 01b, the vector size is 256 bits (sixteen half-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (thirty-two half-precision elements per vector) and register based source operands are held in ZMM registers.

The first and second operands are registers and the third operand is a register, or a memory location, or (for EVEX encodings) a broadcast 16-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by EVEX.L'L. When the destination is an XMM register (L'L = 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L'L = 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions”.

[AMD Public Use]

VFMSUBSS VFMSUB132SS VFMSUB213SS VFMSUB231SS — Multiply and Subtract Scalar Single-Precision Floating-Point

Multiplies together two single-precision floating-point values and subtracts a third single-precision floating-point value from the unrounded product to produce a precise intermediate result. The intermediate result is then rounded to single-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding).and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFMSUBSS dest, src1, src2/mem, src3     // dest = (src1* src2/mem) − src3
VFMSUBSS dest, src1, src2, src3/mem     // dest = (src1* src2) − src3/mem
```

and three three-operand forms:

```
VFMSUB132SS src1, src2, src3/mem        // src1 = (src1* src3/mem) − src2
VFMSUB213SS src1, src2, src3/mem        // src1 = (src2* src1) − src3/mem
VFMSUB231SS src1, src2, src3/mem        // src1 = (src2* src3/mem) − src1
```

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (four single-precision elements per vector) and register based source operands are held in XMM registers.
- When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (eight single-precision elements per vector) and register based source operands are held in YMM registers.
- When EVEX.L'L = 10b, the vector size is 512 bits (sixteen single-precision elements per vector) and register based source operands are held in ZMM registers.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:32] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

			F	CR4.OSXSAVE = 0, indicated by CPUID Fn0000_0001_ECX[OSXSAVE].
			F	XFEATURE_ENABLED_MASK[2:1] ! = 11b.
			F	REX, F2, F3, or 66 prefix preceding VEX prefix.
			F	Lock prefix (F0h) preceding opcode.
			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 0, see *SIMD Floating-Point Exceptions* below for details.
Device not available, #NM			F	CR0.TS = 1.
Stack, #SS			F	Memory address exceeding stack segment limit or non-canonical.
General protection, #GP			F	Memory address exceeding data segment limit or non-canonical.
			F	Null data segment used to reference memory.
Page fault, #PF			F	Instruction execution caused a page fault.
Alignment check, #AC			F	Non-aligned memory reference when alignment checking enabled.
SIMD floating-point, #XF			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid operation, IE			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VFMULCPH — Complex Multiply on Packed Half-Precision Data

Perform a complex multiply operation on each complex number in the data. Each complex number consists of an even/odd pair of half-precision floating point values. The even of the pair is the real portion of the complex number. The odd of the pair is the inaginary portion of the complex number.

The operation performed is (where .r indicates the real portion and .i indicates the imaginary portion of the complex number):

```
dest.r = src1.r * src2.r - src1.i * src2.i
dest.i = src1.i * src2.r + src1.r * src2.i
```

The operation is done in two operations. The first operation is a multiply performing the first multiplies in the above equations. The second operation is a fused-multiply-add performing the second multiplies in the above equation and adding/subtracting it to/from the result of the first operation.

This has implications, some of which include:

- The result of the first operation will be rounded before being input into the second operation.
- An overflow generated by the first operation cannot be brought back in range by the second operation.
- A Denorm generated by the first operation, input into the second operation will cause MXCSR.DE to be set.

There are only extended forms of this instruction:

VFMULCPH

The extended form of the instruction has 128-bit, 256-bit and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register corresponding to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register corresponding to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is either a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

VFMULCSH Complex Multiply on Scalar Half-Precision Data

Perform a complex multiply operation on the low complex number in the data. Each complex number consists of an even/odd pair of half-precision floating point values. The even of the pair is the real portion of the complex number. The odd of the pair is the inaginary portion of the complex number.

The operation performed is (where .r indicates the real portion and .i indicates the imaginary portion of the complex number):

```
dest.r = src1.r * src2.r - src1.i * src2.i
dest.i = src1.i * src2.r + src1.r * src2.i
```

The operation is done in two operations. The first operation is a multiply performing the first multiplies in the above equations. The second operation is a fused-multiply-add performing the second multiplies in the above equation and adding/subtracting it to/from the result of the first operation.

This has implications, some of which include:

- The result of the first operation will be rounded before being input into the second operation.
- An overflow generated by the first operation cannot be brought back in range by the second operation.
- A Denorm generated by the first operation, input into the second operation will cause MXCSR.DE to be set.

There are only extended forms of this instruction:

VFMULCSH

The extended form of the instruction has 128-bit, 256-bit and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register, a 32-bit memory location. The destination is a third XMM register. Bits [127:32] of the first source operand are copied to bits [127:32] of the destination. Bits above bit 127 of the YMM/ZMM register corresponding to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register, a 32-bit memory location. The destination is a third YMM register. Bits [127:32] of the first source operand are copied to bits [127:32] of the destination. Bits above bit 255 of the ZMM register corresponding to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is either a ZMM register, a 32-bit memory location. The destination is a third ZMM register. Bits [127:32] of the first source operand are copied to bits [127:32] of the destination.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

VFNMADDPD VFNMADD132PD VFNMADD213PD VFNMADD231PD — Negative Multiply and Add Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors, negates the unrounded product, and adds it to a third double-precision floating-point vector. The precise result is then rounded to double-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFNMADDPD dest, src1, src2/mem, src3      // dest = −(src1* src2/mem) + src3
VFNMADDPD dest, src1, src2, src3/mem      // dest = −(src1* src2) + src3/mem
```

and three three-operand forms:

```
VFNMADD132PD src1, src2, src3/mem         // src1 = −(src1* src3/mem) + src2
VFNMADD213PD src1, src2, src3/mem         // src1 = −(src2* src1) + src3/mem
VFNMADD231PD src1, src2, src3/mem         // src1 = −(src2* src3/mem) + src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two double-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four double-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight double-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 64-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by VEX.L or EVEX.L'L. When the destination is an XMM register (L = 0 or L'L == 00b), bits [255512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L = 1 or L'L == 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

Exceptions

Exception	Mode			Cause of Exception
	Real	Virt	Prot	
Invalid opcode, #UD			F	Instruction not supported, as indicated by CPUID feature identifier.
	F	F		FMA instructions are only recognized in protected mode.
			F	CR4.OSXSAVE = 0, indicated by CPUID Fn0000_0001_ECX[OSXSAVE].
			F	XFEATURE_ENABLED_MASK[2:1] ! = 11b.
			F	REX, F2, F3, or 66 prefix preceding VEX prefix.
			F	Lock prefix (F0h) preceding opcode.
			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 0, see *SIMD Floating-Point Exceptions* below for details.
Device not available, #NM			F	CR0.TS = 1.
Stack, #SS			F	Memory address exceeding stack segment limit or non-canonical.
General protection, #GP			F	Memory address exceeding data segment limit or non-canonical.
			F	Null data segment used to reference memory.
Page fault, #PF			F	Instruction execution caused a page fault.
Alignment check, #AC			F	Memory operand not 16-byte aligned when alignment checking enabled.
SIMD floating-point, #XF			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid operation, IE			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VFNMADD132PH VFNMADD213PH VFNMADD231PH — Negative Multiply and Add Packed Half-Precision Floating-Point

Multiplies together two half-precision floating-point vectors, negates the unrounded product, and adds it to a third half-precision floating-point vector. The precise result is then rounded to half-precision based on the mode specified by {er} (if specified) or by MXCSR.RC, and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are three three-operand forms:

```
VFNMADD132PH src1, src2, src3/mem    // src1 = −(src1* src3/mem) + src2
VFNMADD213PH src1, src2, src3/mem    // src1 = −(src2* src1) + src3/mem
VFNMADD231PH src1, src2, src3/mem    // src1 = −(src2* src3/mem) + src1
```

When EVEX.L'L = 00b, the vector size is 128 bits (eight half-precision elements per vector) and register based source operands are held in XMM registers.

When EVEX.L'L = 01b, the vector size is 256 bits (sixteen half-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (thirty-two half-precision elements per vector) and register based source operands are held in ZMM registers.

The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 16-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:16] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Note: *A flag that may be set or cleared is M (modified). Unaffected flags are blank.*																

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions”.

[AMD Public Use]

VFNMADDPS VFNMADD132PS VFNMADD213PS VFNMADD231PS — Negative Multiply and Add Packed Single-Precision Floating-Point

Multiplies together two single-precision floating-point vectors, negates the unrounded product, and adds it to a third single-precision floating-point vector. The precise result is then rounded to single-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFNMADDPS dest, src1, src2/mem, src3      // dest = −(src1* src2/mem) + src3
VFNMADDPS dest, src1, src2, src3/mem      // dest = −(src1* src2) + src3/mem
```

and three three-operand forms:

```
VFNMADD132PS src1, src2, src3/mem         // src1 = −(src1* src3/mem) + src2
VFNMADD213PS src1, src2, src3/mem         // src1 = −(src2* src1) + src3/mem
VFNMADD231PS src1, src2, src3/mem         // src1 = −(src2* src3/mem) + src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (four single-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (eight single-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (sixteen single-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:32] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

VFNMADDSD VFNMADD132SD VFNMADD213SD VFNMADD231SD — Negative Multiply and Add Scalar Double-Precision Floating-Point

Multiplies together two double-precision floating-point values, negates the unrounded product, and adds it to a third double-precision floating-point value. The precise result is then rounded to double-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

```
VFNMADDSD dest, src1, src2/mem, src3      // dest = −(src1* src2/mem) + src3
VFNMADDSD dest, src1, src2, src3/mem      // dest = −(src1* src2) + src3/mem
```

and three three-operand forms:

```
VFNMADD132SD src1, src2, src3/mem         // src1 = −(src1* src3/mem) + src2
VFNMADD213SD src1, src2, src3/mem         // src1 = −(src2* src1) + src3/mem
VFNMADD231SD src1, src2, src3/mem         // src1 = −(src2* src3/mem) + src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two double-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four double-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight double-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or 64-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or 64-bit memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 64-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:64] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

Instruction Support

Form	Subset
VEX VFNMADDSD	FMA4
VEX VFNMADD*nnn*SD	FMA
EVEX VFNMADD*nnn*SD	AVX512F

[AMD Public Use]

VFNMADDSS VFNMADD132SS VFNMADD213SS VFNMADD231SS — Negative Multiply and Add Scalar Single-Precision Floating-Point

Multiplies together two single-precision floating-point values, negates the unrounded product, and adds it to a third single-precision floating-point value. The precise result is then rounded to single-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

```
VFNMADDSS dest, src1, src2/mem, src3      // dest = −(src1* src2/mem) + src3
VFNMADDSS dest, src1, src2, src3/mem      // dest = −(src1* src2) + src3/mem
```

and three three-operand forms:

```
VFNMADD132SS src1, src2, src3/mem         // src1 = −(src1* src3/mem) + src2
VFNMADD213SS src1, src2, src3/mem         // src1 = −(src2* src1) + src3/mem
VFNMADD231SS src1, src2, src3/mem         // src1 = −(src2* src3/mem) + src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (four single-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (eight single-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (sixteen single-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or 32-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or 32-bit memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:32] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

[AMD Public Use]

VFNMSUBPD VFNMSUB132PD VFNMSUB213PD VFNMSUB231PD — Negative Multiply and Subtract Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors, negates the unrounded product, and subtracts a third double-precision floating-point vector from it. The precise result is then rounded to double-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFNMSUBPD dest, src1, src2/mem, src3      // dest = −(src1* src2/mem) − src3
VFNMSUBPD dest, src1, src2, src3/mem      // dest = −(src1* src2) − src3/mem
```

and three three-operand forms:

```
VFNMSUB132PD src1, src2, src3/mem         // src1 = −(src1* src3/mem) − src2
VFNMSUB213PD src1, src2, src3/mem         // src1 = −(src2* src1) − src3/mem
VFNMSUB231PD src1, src2, src3/mem         // src1 = −(src2* src3/mem) − src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two double-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four double-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight double-precision elements per vector) and register based source operands are held in ZMM registers..

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 64-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by VEX.L or EVEX.L'L. When the destination is an XMM register (L = 0 or L'L == 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L = 1 or L'L == 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

VFNMSUB132PH VFNMSUB213PH VFNMSUB231PH — Negative Multiply and Subtract Packed Half-Precision Floating-Point

Multiplies together two half-precision floating-point vectors, negates the unrounded product, and subtracts a third half-precision floating-point vector from it. The precise result is then rounded to half-precision based on the mode specified by {er} (if specified) or by MXCSR.RC, and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are three three-operand forms:

```
VFNMSUB132PH src1, src2, src3/mem    // src1 = −(src1* src3/mem) − src2
VFNMSUB213PH src1, src2, src3/mem    // src1 = −(src2* src1) − src3/mem
VFNMSUB231PH src1, src2, src3/mem    // src1 = −(src2* src3/mem) − src1
```

When EVEX.L'L = 00b, the vector size is 128 bits (eight half-precision elements per vector) and register based source operands are held in XMM registers.

When EVEX.L'L = 01b, the vector size is 256 bits (sixteen half-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (thirty-two half-precision elements per vector) and register based source operands are held in ZMM registers.

The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 16-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by EVEX.L'L. When the destination is an XMM register (L'L = 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L'L = 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Note: *A flag that may be set or cleared is M (modified). Unaffected flags are blank.*

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions”.

[AMD Public Use]

VFNMSUB132SH VFNMSUB213SH VFNMSUB231SH — Negative Multiply and Subtract Scalar Half-Precision Floating-Point

Multiplies together two half-precision floating-point values, negates the unrounded product, and subtracts a third half-precision floating-point value from it. The precise result is then rounded to half-precision based on the mode specified by {er} (if specified) or by MXCSR.RC, and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are three three-operand forms:

```
VFNMSUB132SH src1, src2, src3/mem    // src1 = −(src1* src3/mem) − src2
VFNMSUB213SH src1, src2, src3/mem    // src1 = −(src2* src1) − src3/mem
VFNMSUB231SH src1, src2, src3/mem    // src1 = −(src2* src3/mem) − src1
```

When EVEX.L’L = 00b, the vector size is 128 bits (eight half-precision elements per vector) and register based source operands are held in XMM registers.

When EVEX.L’L = 01b, the vector size is 256 bits (sixteen sign-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L’L = 10b, the vector size is 512 bits (thirty-two half-precision elements per vector) and register based source operands are held in ZMM registers.

The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 16-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:16] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions”.

[AMD Public Use]

VFNMSUBPS VFNMSUB132PS VFNMSUB213PS VFNMSUB231PS — Negative Multiply and Subtract Packed Single-Precision Floating-Point

Multiplies together two single-precision floating-point vectors, negates the unrounded product, and subtracts a third single-precision floating-point vector from it. The precise result is then rounded to single-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFNMSUBPS dest, src1, src2/mem, src3      // dest = −(src1* src2/mem) − src3
VFNMSUBPS dest, src1, src2, src3/mem      // dest = −(src1* src2) − src3/mem
```

and three three-operand forms:

```
VFNMSUB132PS src1, src2, src3/mem         // src1 = −(src1* src3/mem) − src2
VFNMSUB213PS src1, src2, src3/mem         // src1 = −(src2* src1) − src3/mem
VFNMSUB231PS src1, src2, src3/mem         // src1 = −(src2* src3/mem) − src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (four single-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (eight single-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (sixteen single-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The destination is an XMM register, a YMM register, or a ZMM register, as determined by VEX.L or EVEX.L'L. When the destination is an XMM register (L = 0 or L'L == 00b), bits [512:128] of the corresponding YMM/ZMM register are cleared. When the destination is a YMM register (L = 1 or L'L == 01b), bits [512:255] of the corresponding ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

			F	XFEATURE_ENABLED_MASK[2:1] ! = 11b.
			F	REX, F2, F3, or 66 prefix preceding VEX prefix.
			F	Lock prefix (F0h) preceding opcode.
			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 0, see *SIMD Floating-Point Exceptions* below for details.
Device not available, #NM			F	CR0.TS = 1.
Stack, #SS			F	Memory address exceeding stack segment limit or non-canonical.
General protection, #GP			F	Memory address exceeding data segment limit or non-canonical.
			F	Null data segment used to reference memory.
Page fault, #PF			F	Instruction execution caused a page fault.
Alignment check, #AC			F	Memory operand not 16-byte aligned when alignment checking enabled.
SIMD floating-point, #XF			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid operation, IE			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VFNMSUBSD VFNMSUB132SD VFNMSUB213SD VFNMSUB231SD — Negative Multiply and Subtract Scalar Double-Precision Floating-Point

Multiplies together two double-precision floating-point values, negates the unrounded product, and subtracts a third double-precision floating-point value from it. The precise result is then rounded to double-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

```
VFNMSUBSD dest, src1, src2/mem, src3      // dest = −(src1* src2/mem) − src3
VFNMSUBSD dest, src1, src2, src3/mem      // dest = −(src1* src2) − src3/mem
```

and three three-operand forms:

```
VFNMSUB132SD src1, src2, src3/mem         // src1 = −(src1* src3/mem) − src2
VFNMSUB213SD src1, src2, src3/mem         // src1 = −(src2* src1) − src3/mem
VFNMSUB231SD src1, src2, src3/mem         // src1 = −(src2* src3/mem) − src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (two double-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (four double-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (eight double-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a 64-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a 64-bit memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 64-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:64] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

VFNMSUBSS VFNMSUB132SS VFNMSUB213SS VFNMSUB231SS — Negative Multiply and Subtract Scalar Single-Precision Floating-Point

Multiplies together two single-precision floating-point values, negates the unrounded product, and subtracts a third single-precision floating-point value from it. The precise result is then rounded to single-precision based on the mode specified by the MXCSR[RC] field or a specified {er} (for forms supporting explicit rounding) and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

```
VFNMSUBSS dest, src1, src2/mem, src3      // dest = −(src1* src2/mem) − src3
VFNMSUBSS dest, src1, src2, src3/mem      // dest = −(src1* src2) − src3/mem
```

and three three-operand forms:

```
VFNMSUB132SS src1, src2, src3/mem         // src1 = −(src1* src3/mem) − src2
VFNMSUB213SS src1, src2, src3/mem         // src1 = −(src2* src1) − src3/mem
VFNMSUB231SS src1, src2, src3/mem         // src1 = −(src2* src3/mem) − src1
```

When VEX.L = 0 or EVEX.L'L = 00b, the vector size is 128 bits (four single-precision elements per vector) and register based source operands are held in XMM registers.

When VEX.L = 1 or EVEX.L'L = 01b, the vector size is 256 bits (eight sign-precision elements per vector) and register based source operands are held in YMM registers.

When EVEX.L'L = 10b, the vector size is 512 bits (sixteen single-precision elements per vector) and register based source operands are held in ZMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is a register or a 32-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or a 32-bit memory location.

For the three-operand forms, (E)VEX.W is 1. The first and second operands are registers and the third operand is a register, a memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:32] of the destination and bits [512:128] of the corresponding YMM/ZMM register are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VFPCLASSPD Classify Packed Double Precision Floating Point Values

Classify packed double precision floating point elements for various special values of the element, writing the results to a K mask register.

Eight different classifications of data are each enabled with one of the 8 bits of the immediate operand as follows:

Immediate Bit	Class
0	QNaN
1	+0.0
2	-0.0
3	+Inf
4	-Inf
5	Denormal
6	Negative Finite Number
7	SNaN

All enabled checks are performed for each input element in the source operand. The results of all enabled checks for each element are OR-ed together into a single bit which is written to the destination K mask register.

There are only extended forms of this instruction:

VFPCLASSPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a K mask register. Bits above bit 1 in the destination are cleared.

YMM Encoding

The source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a K mask register. Bits above bit 3 in the destination are cleared.

ZMM Encoding

The source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a K mask register. Bits above bit 7 in the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression..

[AMD Public Use]

VFRCZPD — Extract Fraction Packed Double-Precision Floating-Point

Extracts the fractional portion of each double-precision floating-point value of either a source register or a memory location and writes the resulting values to the corresponding elements of the destination. The fractional results are precise.

- When XOP.L = 0, the source is an XMM register or a 128-bit memory location.
- When XOP.L = 1, the source is a YMM register or 256-bit memory location.

When the destination is an XMM register, above bit 127 of the corresponding ZMM/YMM register are cleared.

Exception conditions are the same as for other arithmetic instructions, except with respect to the sign of a zero result. A zero is returned in the following cases:

- When the operand is a zero.
- When the operand is a normal integer.
- When the operand is a denormal value and is coerced to zero by MXCSR.DAZ.
- When the operand is a denormal value that is not coerced to zero by MXCSR.DAZ.

In the first three cases, when MXCSR.RC = 01b (round toward – ∞) the sign of the zero result is negative, and is otherwise positive.

In the fourth case, the operand is its own fractional part, which results in underflow, and the result is forced to zero by MXCSR.FZ; the result has the same sign as the operand.

Instruction Support

[AMD Public Use]

VFRCZPS Extract Fraction Packed Single-Precision Floating-Point

Extracts the fractional portion of each single-precision floating-point value of either a source register or a memory location and writes the resulting values to the corresponding elements of the destination. The fractional results are exact.

- When XOP.L = 0, the source is an XMM register or a 128-bit memory location.
- When XOP.L = 1, the source is a YMM register or 256-bit memory location.

When the destination is an XMM register, bits above bit 127 of the corresponding ZMM/YMM register are cleared.

Exception conditions are the same as for other arithmetic instructions, except with respect to the sign of a zero result. A zero is returned in the following cases:

- When the operand is a zero.
- When the operand is a normal integer.
- When the operand is a denormal value and is coerced to zero by MXCSR.DAZ.
- When the operand is a denormal value that is not coerced to zero by MXCSR.DAZ.

In the first three cases, when MXCSR.RC = 01b (round toward – ∞) the sign of the zero result is negative, and is otherwise positive.

In the fourth case, the operand is its own fractional part, which results in underflow, and the result is forced to zero by MXCSR.FZ; the result has the same sign as the operand.

Precision, PE			X	A result could not be represented exactly in the destination format.
X — XOP exception				

[AMD Public Use]

VFRCZSD Extract Fraction Scalar Double-Precision Floating-Point

Extracts the fractional portion of the double-precision floating-point value of either the low-order quadword of an XMM register or a 64-bit memory location and writes the result to the low-order quadword of the destination XMM register. The fractional results are precise.

When the result is written to the destination XMM register, Bits [127:64] of the destination and bits above bit 127 of the corresponding ZMM/YMM register are cleared.

Exception conditions are the same as for other arithmetic instructions, except with respect to the sign of a zero result. A zero is returned in the following cases:

- When the operand is a zero.
- When the operand is a normal integer.
- When the operand is a denormal value and is coerced to zero by MXCSR.DAZ.
- When the operand is a denormal value that is not coerced to zero by MXCSR.DAZ.

In the first three cases, when MXCSR.RC = 01b (round toward – ∞) the sign of the zero result is negative, and is otherwise positive.

In the fourth case, the operand is its own fractional part, which results in underflow, and the result is forced to zero by MXCSR.FZ; the result has the same sign as the operand.

VFRCZSS Extract Fraction Scalar Single-Precision Floating Point

Extracts the fractional portion of the single-precision floating-point value of the low-order doubleword of an XMM register or 32-bit memory location and writes the result in the low-order doubleword of the destination XMM register. The fractional results are precise.

When the result is written to the destination XMM register, bits [127:32] of the destination and bits above bit 127 of the corresponding ZMM/YMM register are cleared.

Exception conditions are the same as for other arithmetic instructions, except with respect to the sign of a zero result. A zero is returned in the following cases:

- When the operand is a zero.
- When the operand is a normal integer.
- When the operand is a denormal value and is coerced to zero by MXCSR.DAZ.
- When the operand is a denormal value that is not coerced to zero by MXCSR.DAZ.

In the first three cases, when MXCSR.RC = 01b (round toward $-\infty$) the sign of the zero result is negative, and is otherwise positive.

In the fourth case, the operand is its own fractional part, which results in underflow, and the result is forced to zero by MXCSR.FZ; the result has the same sign as the operand.

[AMD Public Use]

VGATHERDPD Conditionally Gather Double-Precision Floating-Point Values, Doubleword Indices

Conditionally loads 2, 4, or 8 double-precision (64-bit) values from memory using VSIB addressing with doubleword indices.

The VEX encoding of the instructions is of the form:

VGATHERDPD dest, mem64[vm32x], mask

The EVEX encoding of the instruction is of the form:

VGATHERDPD dest {k1}, mem64[vm32x/y]

Loading of each element of the destination register is conditional based on the value of the corresponding element of the mask operand. If the most-significant bit of the ith element of the mask is set, the ith element of the destination is loaded from memory using the ith address of the array of effective addresses calculated using VSIB addressing.

The index register is treated as an array of signed 32-bit values. Quadword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 8 for a discussion of the VSIB addressing mode.

There are VEX-encoded and EVEX encoded forms of the instruction:

VEX-Encoded Forms

The destination is an XMM or YMM register. The first source operand is up to four 64-bit values located in memory. The second source operand (the mask) is an XMM or YMM register. The index vector is up to four doublewords of an XMM register.

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The destination is an XMM register. The first source operand is up to two 64-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the two low-order doublewords of an XMM register; the two high-order doublewords of the index register are not used. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 127 of the YMM/ZMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is a YMM register. The source operand is up to four 64-bit values located in memory.

The index vector is the four doublewords of an XMM register.

Bits above bit 255 of the ZMM register that corresponds to the destination and bits above bit 3 of the k-mask register are cleared.

[AMD Public Use]

EVEX-encoded Forms

The destination is an XMM, YMM, or ZMM register, updated according to a mask register 'k1'. The source operand is up to eight 64-bit values located in memory. The index vector is up to eight doublewords of an XMM or YMM register.

VGATHERDPD

The EVEX-encoded form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination is an XMM register. The source operand is up to two 64-bit values located in memory. The index vector is the two low-order doublewords of an XMM register; the two high-order doublewords of the index register are not used. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 1 of the k-mask register are cleared.

YMM Encoding

The destination is a YMM register. The source operand is up to four 64-bit values located in memory. The index vector is the four doublewords of an XMM register. Bits above bit 255 of the ZMM register that corresponds to the destination and bits above bit 3 of the k-mask register are cleared.

ZMM Encoding

The destination is a ZMM register. The source operand is up to eight 64-bit values located in memory. The index vector is the eight doublewords of a YMM register. Bits above bit 7 of the k-mask register are cleared.

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VGATHERDPS Conditionally Gather Single-Precision Floating-Point Values, Doubleword Indices

Conditionally loads four, eight, or sixteen single-precision (32-bit) values from memory using VSIB addressing with doubleword indices.

The VEX encoding of the instructions is of the form:

VGATHERDPS dest, mem32[vm32x/y], mask

The EVEX encoding of the instruction is of the form:

VGATHERDPS dest {k1}, mem32[vm32x/y/z]

Loading of each element of the destination register is conditional based on the value of the corresponding element of the mask operand. For VEX encodings, if the most-significant bit of the ith element of the mask is set, the ith element of the destination is loaded from memory using the ith address of the array of effective addresses calculated using VSIB addressing. For EVEX encodings, the bit of the k-mask corresponding to the lane being set allows for the lane to be loaded from memory using the corresponding effective address calculated using VSIB addressing.

The index register is treated as an array of signed 32-bit values. Doubleword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 8 for a discussion of the VSIB addressing mode.

There are VEX-encoded and EVEX encoded forms of the instruction:

VEX-encoded Forms

The destination is an XMM or YMM register. The first source operand is up to eight 32-bit values located in memory. The second source operand (the mask) is an XMM or YMM register. The index vector is up to eight doublewords of an XMM or YMM register.

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The destination is an XMM register. The first source operand is up to four 32-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the four doublewords of an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 127 of the YMM/ZMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is up to eight 32-bit values located in memory. The second source operand (the mask) is a YMM register. The index vector is the eight doublewords of an XMM register. Bits above bit 255 of the ZMM register that corresponds to the destination and bits above bit 255 of the ZMM register that corresponds to the second source (mask) operand are cleared.

[AMD Public Use]

EVEX-encoded Forms

The destination is an XMM, YMM, or ZMM register, updated according to a mask register 'k1'. The source operand is up to 16 32-bit values located in memory. The index vector is up to 16 doublewords of an XMM, YMM, or ZMM register.

VGATHERDPS

The EVEX-encoded form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination is an XMM register. The source operand is up to four 32-bit values located in memory. The index vector is the four doublewords of an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 3 of the k-mask register are cleared.

YMM Encoding

The destination is a YMM register. The source operand is up to eight 32-bit values located in memory. The index vector is the eight doublewords of a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination and bits above bit 7 of the k-mask register are cleared.

ZMM Encoding

The destination is a ZMM register. The source operand is up to 16 32-bit values located in memory. The index vector is the 16 doublewords of a ZMM register. Bits above bit 15 of the k-mask register are cleared.

[AMD Public Use]

VGATHERQPD Conditionally Gather Double-Precision Floating-Point Values, Quadword Indices

Conditionally loads 2, 4, or 8 double-precision (64-bit) values from memory using VSIB addressing with quadword indices.

The VEX encoding of the instructions is of the form:

VGATHERQPD dest, mem64[vm64x/y], mask

The EVEX encoding of the instruction is of the form:

VGATHERQPD dest {k1}, mem64[vm64x/y/z]

Loading of each element of the destination register is conditional based on the value of the corresponding element of the mask operand. For VEX encodings, if the most-significant bit of the ith element of the mask is set, the ith element of the destination is loaded from memory using the ith address of the array of effective addresses calculated using VSIB addressing. For EVEX encodings, the bit of the k-mask corresponding to the lane being set allows for the lane to be loaded from memory using the corresponding effective address calculated using VSIB addressing.

The index register is treated as an array of signed 64-bit values. Quadword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 8 for a discussion of the VSIB addressing mode.

There are VEX-encoded and EVEX encoded forms of the instruction:

VEX-encoded Forms

The destination is an XMM or YMM register. The first source operand is up to four 64-bit values located in memory. The second source operand (the mask) is an XMM or YMM register. The index vector is up to four quadwords of an XMM/YMM register.

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The destination is an XMM register. The first source operand is up to two 64-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the two quadwords of an XMM register.Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 127 of the YMM/ZMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is up to four 64-bit values located in memory. The second source operand (the mask) is a YMM register. The index vector is the four quadwords of a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination and bits above bit 255 of the ZMM register that corresponds to the second source (mask) operand are cleared.

[AMD Public Use]

EVEX-encoded Forms

The destination is an XMM, YMM, or ZMM register, updated according to a mask register 'k1'. The source operand is up to eight 64-bit values located in memory. The index vector is up to eight quadwords of an XMM, YMM, or ZMM register.

VGATHERQPD

The EVEX-encoded form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination is an XMM register. The source operand is up to two 64-bit values located in memory. The index vector is the two quadwords of an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 1 of the k-mask register are cleared.

YMM Encoding

The destination is a YMM register. The source operand is up to four 64-bit values located in memory. The index vector is the four quadwords of a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination and bits above bit 3 of the k-mask register are cleared.

ZMM Encoding

The destination is a ZMM register. The source operand is up to eight 64-bit values located in memory. The index vector is the eight quadwords of a ZMM register. Bits above bit 7 of the k-mask register are cleared.

A — AVX2 exception				

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VGATHERQPS Conditionally Gather Single-Precision Floating-Point Values, Quadword Indices

Conditionally loads 2, 4, or 8 single-precision (32-bit) values from memory using VSIB addressing with quadword indices.

The VEX encoding of the instructions is of the form:

VGATHERDPD dest, mem32[vm64x/y], mask

The EVEX encoding of the instruction is of the form:

VGATHERDPD dest {k1}, mem32[vm64x/y/z]

Loading of each element of the destination register is conditional based on the value of the corresponding element of the mask operand. For VEX encodings, if the most-significant bit of the ith element of the mask is set, the ith element of the destination is loaded from memory using the ith address of the array of effective addresses calculated using VSIB addressing. For EVEX encodings, the bit of the k-mask corresponding to the lane being set allows for the lane to be loaded from memory using the corresponding effective address calculated using VSIB addressing.

The index register is treated as an array of signed 64-bit values. Doubleword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 8 for a discussion of the VSIB addressing mode.

There are VEX-encoded and EVEX encoded forms of the instruction:

VEX-encoded Forms

The destination is an XMM register. The first source operand is up to four 32-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is up to four doublewords of an XMM or YMM register.

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The destination is an XMM register. The first source operand is up to two 32-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the two doublewords of a YMM register. Bits [127:64] of the destination and bits above bit 127 of the corresponding YMM/ZMM register are cleared. Bits [127:64] of the second source (mask) operand and bits above bit 127 of the corresponding YMM/ZMM register are cleared.

YMM Encoding

The destination is an XMM register. The first source operand is up to four 32-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the four quadwords of a YMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 127 of the YMM/ZMM register that corresponds to the second source (mask) operand are cleared.

[AMD Public Use]

EVEX-encoded Forms

The destination is an XMM, YMM, or ZMM register, updated according to a mask register 'k1'. The source operand is up to eight 32-bit values located in memory. The index vector is up to eight quadwords of an XMM, YMM, or ZMM register.

VGATHERQPS

The EVEX-encoded form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination is an XMM register. The source operand is up to two 32-bit values located in memory. The index vector is the two quadwords of an XMM register. Bits [127:64] of the destination and bits above bit 127 of the corresponding YMM/ZMM register are cleared. Bits above bit 1 of the k-mask register are cleared.

YMM Encoding

The destination is an XMM register. The source operand is up to four 32-bit values located in memory. The index vector is the four quadwords of a YMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 3 of the k-mask register are cleared.

ZMM Encoding

The destination is a YMM register. The source operand is up to eight 32-bit values located in memory. The index vector is the eight quadwords of a ZMM register. Bits above bit 255 of the ZMM register that corresponds to the destination and bits above bit 7 of the k-mask register are cleared.

VGETMANTPD Extract Mantissas from Double Precision Floating Point Values and Convert to Double Precision Floating Point Values

Extract mantissas from the double precision floating point elements, convert them to double precision floating point values, and write them to a double precision floating point element. The extracted mantissa is mapped to the interval specified by imm[1:0] and a sign is assigned based on imm[3:2].

The interval mapped to is determined by imm[1:0] and whether the source exponent is even/odd as follows:

imm[1:0]	Exponent lsb	Interval
00	x	[1, 2)
01	0	[0.5, 1)
01	1	[1, 2)
10	x	[0.5, 1)
11	x	[0.75, 1.5)

Note that the 'exponent lsb' in this table is the least significant bit of the exponent in the source data - a '0' means the exponent is odd, and a '1' means the exponent is even. The destination mantissa will be equal to the source mantissa. The destination exponent will be set to place the destination value in the specified interval.

The destination sign is determined by imm[3:2] and the source sign as follows:

imm[3:2]	Source Sign	Dest. Sign
00	x	Source Sign
01	x	0
1x	1	qNaN
1x	0	0

Special values are processed as specified by the following table:

Source Value	imm[3:2]	Dest. Value
NaN	xx	qNaN
+Inf	xx	+1.0
+0	xx	+1.0
-Inf	00	-1.0
-Inf	01	+1.0
-Inf	1x	-qNaN
-0	x0	-1.0
-0	x1	+1.0

There are only extended forms of this instruction:

VGETMANTPD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

[AMD Public Use]

XMM Encoding

The source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a second XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a second YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a second ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

VGETMANTPH Extract Mantissas from Half-Precision Floating Point Values and Convert to Half-Precision Floating Point Values

Extract mantissas from the half-precision floating point elements, convert them to half-precision floating point values, and write them to a half-precision floating point element. The extracted mantissa is mapped to the interval specified by imm[1:0] and a sign is assigned based on imm[3:2].

The interval mapped to is determined by imm[1:0] and whether the source exponent is even/odd as follows:

imm[1:0]	Exponent lsb	Interval
00	x	[1, 2)
01	0	[0.5, 1)
01	1	[1, 2)
10	x	[0.5, 1)
11	x	[0.75, 1.5)

Note that the 'exponent lsb' in this table is the least significant bit of the exponent in the source data - a '0' means the exponent is odd, and a '1' means the exponent is even. The destination exponent will be set to place the destination value in the

specified interval.

The destination sign is determined by imm[3:2] and the source sign as follows:

imm[3:2]	Source Sign	Dest. Sign
00	x	Source Sign
01	x	0
1x	1	qNaN
1x	0	0

Special values are processed as specified by the following table:

Source Value	imm[3:2]	Dest. Value
NaN	xx	qNaN
+Inf	xx	+1.0
+0	xx	+1.0
-Inf	00	-1.0
-Inf	01	+1.0
-Inf	1x	-qNaN
-0	x0	-1.0
-0	x1	+1.0

VINSERTF128 Insert Packed Floating-Point Values 128-bit

Combines 128 bits of data from a YMM register with 128-bit packed-value data from an XMM register or a 128-bit memory location, as specified by an immediate byte operand, and writes the combined data to the destination.

Only bit [0] of the immediate operand is used. Operation is as follows.

- When imm8[0] = 0, copy bits [255:128] of the first source to bits [255:128] of the destination and copy bits [127:0] of the second source to bits [127:0] of the destination.
- When imm8[0] = 1, copy bits [127:0] of the first source to bits [127:0] of the destination and copy bits [127:0] of the second source to bits [255:128] of the destination.

This extended-form instruction has a single 256-bit encoding:

The first source operand is a YMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a YMM register. There is a third immediate byte operand. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

A — AVX exception.				

[AMD Public Use]

VINSERTF32X4 Insert 4 Packed Single-Precision Floating-Point Values

Copies 128 bits from the second source operand into a 128-bit field of the destination operand as indicated by an immediate operand. Other bits of the destination register are copied from the first source operand.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a ZMM register. Bits [1:0] of the immediate operand select which quarter of the destination register is written with the data from the second source operand.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

Instruction Support

[AMD Public Use]

VINSERTI128 Insert Packed Integer Values 128-bit

Combines 128 bits of data from a YMM register with 128-bit packed-value data from an XMM register or a 128-bit memory location, as specified by an immediate byte operand, and writes the combined data to the destination.

Bit [0] of the immediate operand controls how the 128-bit values from the source operands are merged into the destination. The operation is as follows.

- When imm8[0] = 0, copy bits [255:128] of the first source to bits [255:128] of the destination and copy bits [127:0] of the second source to bits [127:0] of the destination.
- When imm8[0] = 1, copy bits [127:0] of the first source to bits [127:0] of the destination and copy bits [127:0] of the second source to bits [255:128] of the destination.

This instruction has a single 256-bit encoding:

The first source operand is a YMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a YMM register. The immediate byte is encoded in the instruction. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

VMASKMOVPD Masked Move Packed Double-Precision

Moves packed double-precision data elements from a source element to a destination element, as specified by mask bits in a source operand. There are load and store versions of the instruction.

For loads, the data elements are in a source memory location; for stores the data elements are in a source register. The mask bits are the most-significant bit of the corresponding data element of a source register.

- For loads, when a mask bit = 1, the corresponding data element is copied from the source to the same element of the destination; when a mask bit = 0, the corresponding element of the destination is cleared.
- For stores, when a mask bit = 1, the corresponding data element is copied from the source to the same element of the destination; when a mask bit = 0, the corresponding element of the destination is not affected.

Exception and trap behavior for elements not selected for loading or storing from/to memory is implementation dependent. For instance, a given implementation may signal a data breakpoint or a page fault for quadwords that are zero-masked and not actually written.

XMM Encoding

There are load and store encodings.

- For loads, there are two 64-bit source data elements in a 128-bit memory location, the mask operand is an XMM register, and the destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.
- For stores, there are two 64-bit source data elements in an XMM register, the mask operand is an XMM register, and the destination is a 128-bit memory location.

YMM Encoding

There are load and store encodings.

- For loads, there are four 64-bit source data elements in a 256-bit memory location, the mask operand is a YMM register, and the destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.
- For stores, there are four 64-bit source data elements in a YMM register, the mask operand is a YMM register, and the destination is a 128-bit memory location.

VMASKMOVPS Masked Move Packed Single-Precision

Moves packed single-precision data elements from a source element to a destination element, as specified by mask bits in a source operand. There are load and store versions of the instruction.

For loads, the data elements are in a source memory location; for stores the data elements are in a source register. The mask bits are the most-significant bits of the corresponding data element of a source register.

- For loads, when a mask bit = 1, the corresponding data element is copied from the source to the same element of the destination; when a mask bit = 0, the corresponding element of the destination is cleared.
- For stores, when a mask bit = 1, the corresponding data element is copied from the source to the same element of the destination; when a mask bit = 0, the corresponding element of the destination is not affected.

Exception and trap behavior for elements not selected for loading or storing from/to memory is implementation dependent. For instance, a given implementation may signal a data breakpoint or a page fault for doublewords that are zero-masked and not actually written.

XMM Encoding

There are load and store encodings.

- For loads, there are four 32-bit source data elements in a 128-bit memory location, the mask operand is an XMM register, and the destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.
- For stores, there are four 32-bit source data elements in an XMM register, the mask operand is an XMM register, and the destination is a 128-bit memory location.

YMM Encoding

There are load and store encodings.

- For loads, there are eight 32-bit source data elements in a 256-bit memory location, the mask operand is a YMM register, and the destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.
- For stores, there are eight 32-bit source data elements in a YMM register, the mask operand is a YMM register, and the destination is a 128-bit memory location.

[AMD Public Use]

VMAXPH Maximum Packed Half-Precision Floating-Point

Compares each packed half-precision floating-point value of the first source operand to the corresponding value of the second source operand and writes the numerically greater value into the corresponding location of the destination.

If both source operands are equal to zero, the value of the second source operand is returned. If either operand is a NaN (SNaN or QNaN), and invalid-operation exceptions are masked, the second source operand is written to the destination.

There are only extended forms of the instruction:

VMAXPH

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Compares eight pairs of packed half-precision floating-point values. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Compares sixteen pairs of packed half-precision floating-point values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Compares thirty-two pairs of packed half-precision floating-point values. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a ZMM register. The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VMAXSH Maximum Scalar Half-Precision Floating-Point

Compares the scalar half-precision floating-point value in the low-order 16 bits of the first source operand to a corresponding value in the second source operand and writes the numerically greater value into the low-order 16 bits of the destination.

If both source operands are equal to zero, the value of the second source operand is returned. If either operand is a NaN (SNaN or QNaN), and invalid-operation exceptions are masked, the second source operand is written to the destination.

There are only extended forms of the instruction:

VMAXSH

The extended form of the instruction has a 128-bit encoding only. The first source operand is an XMM register. The second source operand is an XMM register or a 16-bit memory location. The destination is an XMM register. Bits [127:16] of the destination are copied from the first source operand. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Instruction Support

Form	Subset
VMAXSH	AVX512_FP16

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VMINPH Minimum Packed Half-Precision Floating-Point

Compares each packed half-precision floating-point value of the first source operand to the corresponding value of the second source operand and writes the numerically lesser value into the corresponding location of the destination.

If both source operands are equal to zero, the value of the second source operand is returned. If either operand is a NaN (SNaN or QNaN), and invalid-operation exceptions are masked, the second source operand is written to the destination.

There are only extended forms of the instruction:

VMINPH

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

Compares eight pairs of packed half-precision floating-point values.

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Compares sixteen pairs of packed half-precision floating-point values. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

Compares thirty-two pairs of packed half-precision floating-point values. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a ZMM register. The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VMOVSH Move Scalar Half-Precision Floating-Point

Moves scalar half-precision floating point values. The source is a low-order word of an XMM register or a 16-bit memory location. The destination is a low-order word of an XMM register or a 16-bit memory location.

There are only extended forms of the instruction:

VMOVSH

The extended form of the instruction has four 128-bit encodings. Two of the encodings are functionally equivalent.

- The source operand is a 16-bit memory location. The destination is an XMM register. The 16-bit value is zero-extended to 128 bits.
- The source operand is an XMM register. The destination is a 16-bit memory location.
- Two functionally equivalent encodings. There are two source XMM registers. The destination is an XMM register. Bits [127:16] of the first source register are copied to bits [127:16] of the destination; the 32-bit value in bits [15:0] of the second source register is written to bits [15:0] of the destination.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

Instruction Support

Form	Subset
VMOVSH	AVX512_FP16

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

[AMD Public Use]

VMOVW Move Word

Move a 16-bit value between an XMM register and a General Purpose Register or a memory location.

There are only extended forms of this instruction:

VMOVW

The extended form of the instruction has two 128-bit encodings:

- The source operand is a general purpose register or a 16-bit memory location. The destination is an XMM register. Bits [127:16] of the destination and bits above bit 127 of the ZMM/YMM register corresponding to the destination are cleared.
- The source operand is an XMM register. The destination is either a general purpose register or a 16-bit memory location. If the destination is a general purpose register, bits above bit 15 of the destination register are cleared.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

[AMD Public Use]

VMULPH Multiply Packed Half-Precision Floating-Point

Multiplies eight, sixteen, or thirty-two packed half-precision floating-point values of the first source operand by the corresponding packed half-precision floating-point value of the second source operand and writes the product of each multiplication into the corresponding elements of the destination.

There are only extended forms of the instruction:

VMULPH

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 16-bit memory location. The destination is a third ZMM register. The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VP2INTERSECTD Compare Doubleword Elements into Two K Registers

Compare each doubleword element in each source to see if it matches any elements in the other source. The results are written into and even/odd pair of K registers. The destination K registers are specified by the ModR/M.reg 3-bit field. The register indicated by that field & 06h is the even destination K register. The register indicated by that field | 01h is the odd destination K register. A bit is written in each destination register for each doubleword element in the source registers. Additional (higher) bits are cleared. Each doubleword element (n) in the first source operand is checked to see if it matches any elements in the second source operand. If there are any matches, bit n of the even destination K register is set. If there are no matches, bit n of the even destination K register is cleared. Each doubleword element (n) in the second source operand is checked to see if it matches any elements in the first source operand. If there are any matches, bit n of the odd destination K register is set. If there are no matches, bit n of the odd destination K register is cleared.

There are only extended forms of this instruction:

VP2INTERSECTD

The extended form of the instruction has 128-bit, 256-bit and 512-bit encodings:

XMM Encoding

The first source operand is an XMM Register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. There are 2 destination registers - an even/odd pair of K registers.

YMM Encoding

The first source operand is a YMM Register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. There are 2 destination registers - an even/odd pair of K registers.

ZMM Encoding

The first source operand is a ZMM Register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. There are 2 destination registers - an even/odd pair of K registers.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

VPABSQ Packed Absolute Value Quadword

Computes the absolute value of two, four or eight packed 64-bit signed integers in the source operand. Each quadword of the destination receives an unsigned 64-bit integer that is the absolute value of the signed 64-bit integer in the corresponding quadword of the source operand.

This instruction has only extended forms and has 128-bit, 256-bit and 512-bit encodings:

XMM Encoding

The source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

VPANDD Packed AND Doubleword

Performs a bitwise AND of four, eight, or sixteen packed doubleword integers in the first and second source operands and writes the result to the destination.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VPANDND

Performs a bitwise AND of four, eight, or sixteen packed doubleword integers in the first and second source operands with the ones'-complement of the corresponding packed single-precision floating-point values in the first source operand, and writes the result in the destination.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

VPANDNQ

Performs a bitwise AND of 2, 4 or 8 packed quadword integers in the first and second source operands with the ones'-complement of the corresponding packed single-precision floating-point values in the first source operand, and writes the result in the destination.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

VPANDQ Packed AND Quadwords

Performs a bitwise AND of 2, 4 or 8 packed quadword integers in the first and second source operands and writes the result to the destination.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

[AMD Public Use]

VPBLENDD Blend Packed Doublewords

Copies packed doublewords from either of two sources to a destination, as specified by an immediate 8-bit mask operand.

Each bit of the mask selects a doubleword from one of the source operands to be copied to the destination. The least-significant bit controls the selection of the doubleword to be copied to the lowest doubleword of the destination. For each doubleword *i* of the destination:

- When mask bit [*i*] = 0, doubleword *i* of the first source operand is copied to the corresponding doubleword of the destination.
- When mask bit [*i*] = 1, doubleword *i* of the second source operand is copied to the corresponding doubleword of the destination.

VPBLENDD

The instruction has 128-bit and 256-bit encoding:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

Instruction Support

[AMD Public Use]

VPBLENDMB Blend Packed Byte Elements Based on Mask

Copies packed byte values from either of two sources to a destination, as specified by a mask operand.

Each mask bit specifies a 8-bit element in a source location and a corresponding 8-bit element in the destination register. When a mask bit = 0, the specified element of the first source is copied to the corresponding element in the destination register. When a mask bit = 1, the specified element of the second source is copied to the corresponding element in the destination register.

Note that this instruction does not use the k mask register (specified in EVEX.aaa) in the usual way. The k mask register bits are used to select between source input elements, not determine whether the result element is written. However, the EVEX.z bit maintains its function in that setting EVEX.z causes an output element to be 0 if its corresponding k mask bit is 0.

This instruction has only extended forms and has 128-bit, 256-bit and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are not affected.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VPBLENDMD Blend Packed Doubleword Elements Based on Mask

Copies packed doubleword values from either of two sources to a destination, as specified by a mask operand.

Each mask bit specifies a 32-bit element in a source location and a corresponding 32-bit element in the destination register. When a mask bit = 0, the specified element of the first source is copied to the corresponding element in the destination register. When a mask bit = 1, the specified element of the second source is copied to the corresponding element in the destination register.

Note that this instruction does not use the k mask register (specified in EVEX.aaa) in the usual way. The k mask register bits are used to select between source input elements, not determine whether the result element is written. However, the EVEX.z bit maintains its function in that setting EVEX.z causes an output element to be 0 if its corresponding k mask bit is 0.

This instruction has only extended forms and has 128-bit, 256-bit and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are not affected.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are not affected.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

VPBROADCASTD Broadcast Packed Doubleword

Loads a doubleword from a register or memory and writes it to all 4 or 8 doublewords of an XMM or YMM register.

This instruction has 128-bit and 256-bit encodings.

XMM Encoding

Copies the source operand to all 4 doublewords of the destination.

The source operand is the least-significant 32 bits of an XMM register or a 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

Copies the source operand to all 8 doublewords of the destination.

The source operand is the least-significant 32 bits of an XMM register or a 32-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are not affected.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

VPBROADCASTMB2Q Broadcast Byte Mask to Quadwords

Zero extend the low byte of the source k register and broadcast it to each quadword element of the destination.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is a k register. The destination is an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a k register. The destination is an YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a k register. The destination is an ZMM register.

The EVEX encoded versions of this instruction do not allow a k-mask to be specified and do not support memory fault suppression.

VPCMOV Vector Conditional Move

Moves bits of either the first source or the second source to the corresponding positions in the destination, depending on the value of the corresponding bit of a third source.

When a bit

of the third source = 1, the corresponding bit of the first source is moved to the destination; when a bit of the third source = 0, the corresponding bit of the second source is moved to the destination.

This instruction directly implements the C-language ternary "?" operation on each source bit.

Arbitrary bit-granular predicates can be constructed by any number of methods, or loaded as constants from memory. This instruction may use the results of any SSE instructions as the predicate in the selector. VPCMPEQB (VPCMPGTB), VPCMPEQW (VPCMPGTW), VPCMPEQD (VPCMPGTD) and VPCMPEQQ (VPCMPGTQ) compare bytes, words, doublewords, quadwords and integers, respectively, and set the predicate in the destination to masks of 1s and 0s accordingly. VCMPPS (VCMPSS) and VCMPPD (VCMPSD) compare word and doubleword floating-point source values, respectively, and provide the predicate for the floating-point instructions.

There are four operands: VPCMOV *dest, src1, src2, src3.*

The first source (*src1*) is an XMM or YMM register specified by XOP.vvvv.

XOP.W and bits [7:4] of an immediate byte (*imm8*) configure *src2* and *src3*:

- When XOP.W = 0, *src2* is a register or a memory location specified by ModRM.r/m and *src3* is a register specified by *imm8[7:4]*.
- When XOP.W = 1, s*rc2* is a register specified by *imm8[7:4]* and *src3* is a register or a memory location specified by ModRM.r/m.

The destination (*dest*) is an XMM or a YMM register, as determined by XOP.L. When the destination is an XMM register, bits above bit 127 of the corresponding ZMM/YMM register are cleared. When the destination is a YMM register, bits above bit 255 of the corresponding ZMM register are cleared.

VPCMPB Compare Signed Bytes to Mask

Compare each signed byte value in source 1 with the corresponding signed byte in source 2. The comparison operation is determined by the immediate byte. A true comparison results in a '1' bit being written to the destination mask register. A false comparison results in a '0' bit being written to the destination mask register.

Bits [2:0] of the immediate byte determine the comparison operation. Bits [7:3] are reserved.

Imm[2:0]	Comparison
0	src1 == src2
1	src1 < src2
2	src1 <= src2
3	false
4	src1 != src2
5	src1 >= src2
6	src1 > src2
7	true

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a K register. Bits above bit 15 of the destination K register are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a K register. Bits above bit 31 of the destination K register are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a K register.

The results bits are AND-ed with the supplied k mask to produce the final value written to the destination k register. This instruction supports memory fault suppression.

4	src1 != src2
5	src1 >= src2
6	src1 > src2
7	true

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a K register. Bits above bit 3 of the destination K register are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a K register. Bits above bit 7 of the destination K register are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a K register. Bits above bit 15 of the destination K register are cleared.

The results bits are AND-ed with the supplied k mask to produce the final value written to the destination k register. This instruction supports memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VPCMPQ Compare Signed Quadword to Mask

Compare each signed quadword value in source 1 with the corresponding signed quadword in source 2. The comparison operation is determined by the immediate byte. A true comparison results in a '1' bit being written to the destination mask register. A false comparison results in a '0' bit being written to the destination mask register.

Bits [2:0] of the immediate byte determine the comparison operation. Bits [7:3] are reserved.

Imm[2:0]	Comparison
0	src1 == src2
1	src1 < src2
2	src1 <= src2
3	false
4	src1 != src2
5	src1 >= src2
6	src1 > src2
7	true

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a K register. Bits above bit 1 of the destination K register are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a K register. Bits above bit 3 of the destination K register are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a K register. Bits above bit 7 of the destination K register are cleared.

The results bits are AND-ed with the supplied k mask to produce the final value written to the destination k register. This instruction supports memory fault suppression.

VPCOMB Compare Vector Signed Bytes

Compares corresponding packed signed bytes in the first and second sources and writes the result of each comparison in the corresponding byte of the destination. The result of each comparison is an 8-bit value of all 1s (TRUE) or all 0s (FALSE).

There are four operands: VPCOMB *dest, src1, src2, imm8*

The destination (*dest*) is an XMM registers specified by ModRM.reg. When the comparison results are written to the destination XMM register, bits above bit 127 of the corresponding ZMM/YMM register are cleared.

The first source (*src1*) is an XMM register specified by the XOP.vvvv field and the second source (*src2*) is an XMM register or a 128-bit memory location specified by the ModRM.r/m field.

The comparison type is specified by bits [2:0] of the immediate-byte operand (*imm8*). Each type has an alias mnemonic to facilitate coding.

imm8[2:0]	Comparison	Mnemonic
000	Less Than	VPCOMLTB
001	Less Than or Equal	VPCOMLEB
010	Greater Than	VPCOMGTB
011	Greater Than or Equal	VPCOMGEB

[AMD Public Use]

VPCOMPRESSB Compressed Packed Byte Data

Select byte elements of the source register whose associated bit of the mask register are ‘1’, and write these selected elements as a single block to the destination. Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select elements of the source, and then the mask value is compressed (by moving all of the ‘1’ bits in the mask down to the lowest bits of the mask) to create a compressed mask to write the destination.When the destination is a register, this compressed mask is used and normal merging masking or zeroing masking occurs. When the destination is memory, this compressed mask is used to write only the selected elements as one block and memory fault suppression is supported, and EVEX.z must be 0.

For example, when compressing the 64 bytes from a ZMM register, if the K mask register is hex 8000000_00001061, the mask bits are “1” for elements 63, 12, 6, 5, and 0. Those elements would be selected from the source register (bits [511:504], [103:96], [55:48], [47:40] and [7:0]) and shifted into bits [39:0] to be written to the destination. A compressed mask of hex 00000000_0000001f is created, and the data is written to the destination based on this compressed mask. If the destination is a register, bits [39:0] are written and bits [511:40] are merged or zeroed based on EVEX.z. If the destination is memory, 5 bytes (40 bits) are written.

The VPEXPANDB instruction is effectively the opposite of the VPCOMPRESSB instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register. The destination is an XMM register or a 128-bit memory location.

YMM Encoding

The source operand is a YMM register. The destination is a YMM register or a 256-bit memory location.

ZMM Encoding

The source operand is a ZMM register. The destination is a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the compressed k mask per 8-bit element and support memory fault suppression.

Instruction Support

Form	Subset

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VPCOMPRESSD Compressed Packed Doubleword Data

Select doubleword elements of the source register whose associated bit of the mask register are ‘1’, and write these selected elements as a single block to the destination. Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select elements of the source, and then the mask value is compressed (by moving all of the ‘1’ bits in the mask down to the lowest bits of the mask) to create a compressed mask to write the destination. When the destination is a register, this compressed mask is used and normal merging masking or zeroing masking occurs. When the destination is memory, this compressed mask is used to write only the selected elements as one block and memory fault suppression is supported, and EVEX.z must be 0.

See the VPCOMPRESSB instruction for an example of how the VPCOMPRESSx instructions work. The VPEXPANDD instruction is effectively the opposite of the VPCOMPRESSD instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register. The destination is an XMM register or a 128-bit memory location.

YMM Encoding

The source operand is a YMM register. The destination is a YMM register or a 256-bit memory location.

ZMM Encoding

The source operand is a ZMM register. The destination is a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the compressed k mask per 32-bit element and support memory fault suppression.

Instruction Support

Form	Subset
EVEX VPCOMPRESSD 128-bit EVEX VPCOMPRESSD 256-bit	AVX512_VL, AVX512F
EVEX VPCOMPRESSD 512-bit	AVX512F

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VPCOMPRESSQ Compressed Packed Byte Quadword Data

Select quadword elements of the source register whose associated bit of the mask register are ‘1’, and write these selected elements as a single block to the destination. Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select elements of the source, and then the mask value is compressed (by moving all of the ‘1’ bits in the mask down to the lowest bits of the mask) to create a compressed mask to write the destination. When the destination is a register, this compressed mask is used and normal merging masking or zeroing masking occurs. When the destination is memory, this compressed mask is used to write only the selected elements as one block and memory fault suppression is supported, and EVEX.z must be 0.

See the VPCOMPRESSB instruction for an example of how the VPCOMPRESSx instructions work. The VPEXPANDQ instruction is effectively the opposite of the VPCOMPRESSQ instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register. The destination is an XMM register or a 128-bit memory location.

YMM Encoding

The source operand is a YMM register. The destination is a YMM register or a 256-bit memory location.

ZMM Encoding

The source operand is a ZMM register. The destination is a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the compressed k mask per 64-bit element and support memory fault suppression.

Instruction Support

Form	Subset
EVEX VPCOMPRESSQ 128-bit EVEX VPCOMPRESSQ 256-bit	AVX512_VL, AVX512F
EVEX VPCOMPRESSQ 512-bit	AVX512F

[AMD Public Use]

VPCOMPRESSW Compressed Packed Word Data

Select word elements of the source register whose associated bit of the mask register are '1', and write these selected elements as a single block to the destination. Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select elements of the source, and then the mask value is compressed (by moving all of the '1' bits in the mask down to the lowest bits of the mask) to create a compressed mask to write the destination. When the destination is a register, this compressed mask is used and normal merging masking or zeroing masking occurs. When the destination is memory, this compressed mask is used to write only the selected elements as one block and memory fault suppression is supported and EVEX.z must be 0.

See the VPCOMPRESSB instruction for an example of how the VPCOMPRESSx instructions work. The VPEXPANDW instruction is effectively the opposite of the VPCOMPRESSW instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register. The destination is an XMM register or a 128-bit memory location.

YMM Encoding

The source operand is a YMM register. The destination is a YMM register or a 256-bit memory location.

ZMM Encoding

The source operand is a ZMM register. The destination is a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the compressed k mask per 16-bit element and support memory fault suppression.

Instruction Support

Form	Subset
EVEX VPCOMPRESSW 128-bit EVEX VPCOMPRESSW 256-bit	AVX512_VBMI2, AVX512VL
EVEX VPCOMPRESSW 512-bit	AVX512_VBMI2

[AMD Public Use]

VPCOMQ Compare Vector Signed Quadwords

Compares corresponding packed signed quadwords in the first and second sources and writes the result of each comparison to the corresponding quadword of the destination. The result of each comparison is a 64-bit value of all 1s (TRUE) or all 0s (FALSE).

There are four operands: VPCOMQ *dest, src1, src2, imm8*

The destination (*dest*) is an XMM register specified by ModRM.reg. When the result is written to the destination XMM register, bits above bit 127 of the corresponding ZMM/YMM register are cleared.

The first source (*src1*) is an XMM register specified by the XOP.vvvv field and the second source (*src2*) is an XMM register or a 128-bit memory location specified by the ModRM.r/m field.

The comparison type is specified by bits [2:0] of an immediate-byte operand (*imm8)*. Each type has an alias mnemonic to facilitate coding.

imm8[2:0]	Comparison	Mnemonic
000	Less Than	VPCOMLTQ
001	Less Than or Equal	VPCOMLEQ
010	Greater Than	VPCOMGTQ
011	Greater Than or Equal	VPCOMGEQ
100	Equal	VPCOMEQQ
101	Not Equal	VPCOMNEQQ

VPCOMUB Compare Vector Unsigned Bytes

Compares corresponding packed unsigned bytes in the first and second sources and writes the result of each comparison to the corresponding byte of the destination. The result of each comparison is an 8-bit value of all 1s (TRUE) or all 0s (FALSE).

There are four operands: VPCOMUB *dest, src1, src2, imm8*

The destination (*dest*) is an XMM register specified by ModRM.reg. When the result is written to the destination XMM register, bits above bit 127 of the corresponding ZMM/YMM register are cleared.

The first source (*src1*) is an XMM register specified by the XOP.vvvv field and the second source (*src2*) is an XMM register or a 128-bit memory location specified by the ModRM.r/m field.

The comparison type is specified by bits [2:0] of an immediate-byte operand (*imm8)*. Each type has an alias mnemonic to facilitate coding.

VPCONFLICTD Detect Duplicate 32-bit Elements

Compare each 32-bit element in the source operand with every lower element in the same operand. The destination element is written with the results of these comparisons, one bit for each comparison. A ‘1’ bit indicates that the elements match. A ‘0’ bit indicates that the elements do not match, or that no compare was done. Bit 0 indicates if the element matches element 0, bit 1 indicates if the element matches element 1, and so on. Note that output element 0 will always be all 0’s since there are no lower elements to compare input element 0 against (if the mask bit is ‘1’ or masking is turned off).

There are only extended forms of the instruction:

VPCONFLICTD

The instruction has extended form 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VPCONFLICTQ Detect Duplicate 64-bit Elements

Compare each 64-bit element in the source operand with every lower element in the same operand. The destination element is written with the results of these comparisons, one bit for each comparison. A ‘1’ bit indicates that the elements match. A ‘0’ bit indicates that the elements do not match, or that no compare was done. Bit 0 indicates if the element matches element 0, bit 1 indicates if the element matches element 1, and so on. Note that output element 0 will always be all 0’s since there are no lower elements to compare input element 0 against (if the mask bit is ‘1’ or masking is turned off).

There are only extended forms of the instruction:

VPCONFLICTQ

The instruction has extended form 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register, which is also the destination. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register, which is also the destination. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register, which is also the destination. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VPDPWSSDS Dot Product of Signed and Signed Words Summed into Doubleword with Saturation

For each 32-bit lane, multiply each signed word in that lane in source 2 with the corresponding signed word in source 3, sum the products into the signed doubleword in source 1, which is also the destination. If the result overflows a 32-bit doubleword, it is saturated to 7fffffffh for positive numbers or 80000000h for negative numbers.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register, which is also the destination. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register, which is also the destination. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register, which is also the destination. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

Exceptions

Exceptions for AVX512 instructions are enumerated in Section 3.2, “AVX512 Exceptions,” on page 1878.

[AMD Public Use]

VPERM2F128 Permute Floating-Point 128-bit

Copies 128 bits of floating-point data from a selected octword of two 256-bit source operands or zero to each octword of a 256-bit destination, as specified by an immediate byte operand.

The immediate operand is encoded as follows.

Destination	Immediate-Byte Bit Field	Value of Bit Field	Source 1 Bits Copied	Source 2 Bits Copied
[127:0]	[1:0]	00	[127:0]	—
		01	[255:128]	—
		10	—	[127:0]
		11	—	[255:128]
Setting *imm8* [3] clears bits [127:0] of the destination; i*mm8* [2] is ignored.				
[255:128]	[5:4]	00	[127:0]	—
		01	[255:128]	—
		10	—	[127:0]
		11	—	[255:128]
Setting *imm8* [7] clears bits [255:128] of the destination; i*mm8* [6] is ignored.				

This is a 256-bit extended-form instruction:

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register.

VPERMB Packed Permute Bytes

For each destination 8-bit lane, use the low 4, 5 or 6 bits of the byte in the corresponding byte lane in source 1 as a selector to select a byte in source 2 to copy into the destination lane. 128-bit forms use 4 bit selectors to select one of 16 bytes. 256-bit forms use 5 bit selectors to select one of 32 bytes. 512-bit forms use 6 bit selectors to select one of 64 bytes.

The selector may be the same in multiple lanes. This results in multiple copies of the same source byte being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and do not support memory fault suppression.

[AMD Public Use]

VPERMD Packed Permute Doubleword

Copies selected doublewords from a 256/512-bit value located either in memory or a YMM/ZMM register to specific doublewords of the destination YMM/ZMM register. The first source operand provides 3-bit selectors for 256-bit values or 4-bit selectors for 512-bit values. Each selector occupies the least-significant bits of a doubleword and specifies the index of the doubleword of the second source operand to be copied to the destination. The position of the doubleword containing the selector in the first source operand corresponds to the doubleword it controls in the destination. The index value may be the same in multiple selectors. This results in multiple copies of the same source doubleword being copied to the destination.

This instruction has 256-bit and 512-bit forms. There is no 128-bit form.

YMM Encoding

The destination is a YMM register. The first source operand is a YMM register and the second source operand is either a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination is a ZMM register. The first source operand is a ZMM register and the second source operand is either a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

VPERMI2B Permute Byte values from Two Tables Overwrite Index

Each destination byte is copied from a byte in either the second source operand (table0) or the third source operand (table1) based on the value of a selector from a byte in the first source operand. The first source operand is also the destination and provides selectors that are 5-bits for 128-bit operations, 6-bits for 256-bit operations, or 7-bits for 512-bit operations. Each selector occupies the least-significant bits of a byte and specifies the source and index position of the byte to be copied to the destination. The position of the byte containing the selector corresponds to the byte it controls in the destination. The second source operand is the first source table. The third source operand is the second source table. The top bit of the selector selects the source of the data for that lane. A 0 selects the second source operand and a 1 selects the third source operand. The remaining bits of the selector select which byte lane in that source from which to copy the data. The selector may be the same in multiple lanes. This results in multiple copies of the same source byte being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit forms:

VPERMI2B

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination/first source operand is an XMM register. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination/first source operand is a YMM register. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination/first source operand is a ZMM register. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and do not support memory fault suppression.

VPERMI2D Permute Doubleword values from Two Tables Overwrite Index

Each destination doubleword is copied from a doubleword in either the second source operand (table0) or the third source operand (table1) based on the value of a selector from a doubleword in the first source operand. The first source operand is also the destination and provides selectors that are 3-bits for 128-bit operations, 4-bits for 256-bit operations, or 5-bits for 512-bit operations. Each selector occupies the least-significant bits of a doubleword and specifies the source and index position of the doubleword to be copied to the destination. The position of the doubleword containing the selector corresponds to the doubleword it controls in the destination. The second source operand is the first source table. The third source operand is the second source table. The top bit of the selector selects the source of the data for that lane. A 0 selects the second source operand and a 1 selects the third source operand. The remaining bits of the selector select which doubleword lane in that source from which to copy the data. The selector may be the same in multiple lanes. This results in multiple copies of the same source doubleword being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit forms:

VPERMI2D

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination/first source operand is an XMM register. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination/first source operand is a YMM register. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination/first source operand is a ZMM register. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

VPERMI2PD Permute Double precision floating point values from Two Tables Overwrite Index

Each destination double precision floating point value is copied from a quadword in either the second source operand (table0) or the third source operand (table1) based on the value of a selector from a quadword in the first source operand. The first source operand is also the destination and provides selectors that are 2-bits for 128-bit operations, 3-bits for 256-bit operations, or 4-bits for 512-bit operations. Each selector occupies the least-significant bits of a quadword and specifies the source and index position of the quadword to be copied to the destination. The position of the quadword containing the selector corresponds to the double precision floating point value it controls in the destination. The second source operand is the first source table. The third source operand is the second source table. The top bit of the selector selects the source of the data for that lane. A 0 selects the second source operand and a 1 selects the third source operand. The remaining bits of the selector select which quadword lane in that source from which to copy the data. The selector may be the same in multiple lanes. This results in multiple copies of the same source quadword being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit forms:

VPERMI2PD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination/first source operand is an XMM register. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination/first source operand is a YMM register. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination/first source operand is a ZMM register. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

[AMD Public Use]

VPERMI2PS Permute Single precision floating point values from Two Tables Overwrite Index

Each destination single precision floating point value is copied from a doubleword in either the second source operand (table0) or the third source operand (table1) based on the value of a selector from a doubleword in the first source operand. The first source operand is also the destination and provides selectors that are 3-bits for 128-bit operations, 4-bits for 256-bit operations, or 5-bits for 512-bit operations. Each selector occupies the least-significant bits of a doubleword and specifies the source and index position of the doubleword to be copied to the destination. The position of the doubleword containing the selector corresponds to the single precision floating point value it controls in the destination. The second source operand is the first source table. The third source operand is the second source table. The top bit of the selector selects the source of the data for that lane. A 0 selects the second source operand and a 1 selects the third source operand. The remaining bits of the selector select which doubleword lane in that source from which to copy the data. The selector may be the same in multiple lanes. This results in multiple copies of the same source doubleword being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit forms:

VPERMI2PS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination/first source operand is an XMM register. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination/first source operand is a YMM register. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination/first source operand is a ZMM register. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

VPERMI2Q Permute Quadword values from Two Tables Overwrite Index

Each destination quadword is copied from a quadword in either the second source operand (table0) or the third source operand (table1) based on the value of a selector from a quadword in the first source operand. The first source operand is also the destination and provides selectors that are 2-bits for 128-bit operations, 3-bits for 256-bit operations, or 4-bits for 512-bit operations. Each selector occupies the least-significant bits of a quadword and specifies the source and index position of the quadword to be copied to the destination. The position of the quadword containing the selector corresponds to the quadword it controls in the destination. The second source operand is the first source table. The third source operand is the second source table. The top bit of the selector selects the source of the data for that lane. A 0 selects the second source operand and a 1 selects the third source operand. The remaining bits of the selector select which quadword lane in that source from which to copy the data. The selector may be the same in multiple lanes. This results in multiple copies of the same source quadword being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit forms:

VPERMI2Q

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination/first source operand is an XMM register. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination/first source operand is a YMM register. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination/first source operand is a ZMM register. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

VPERMI2W Permute Word values from Two Tables Overwrite Index

Each destination word is copied from a word in either the second source operand (table0) or the third source operand (table1) based on the value of a selector from a word in the first source operand. The first source operand is also the destination and provides selectors that are 4-bits for 128-bit operations, 5-bits for 256-bit operations, or 6-bits for 512-bit operations. Each selector occupies the least-significant bits of a word and specifies the source and index position of the word to be copied to the destination. The position of the word containing the selector corresponds to the word it controls in the destination. The second source operand is the first source table. The third source operand is the second source table. The top bit of the selector selects the source of the data for that lane. A 0 selects the second source operand and a 1 selects the third source operand. The remaining bits of the selector select which word lane in that source from which to copy the data. The selector may be the same in multiple lanes. This results in multiple copies of the same source word being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit forms:

VPERMI2W

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination/first source operand is an XMM register. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination/first source operand is a YMM register. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination/first source operand is a ZMM register. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and do not support memory fault suppression.

VPERMIL2PD — Permute Two-Source Double-Precision Floating-Point

Copies a selected quadword from one of two source operands to a selected quadword of the destination or clears the selected quadword of the destination. Values in a third source operand and an immediate two-bit operand control the operation.

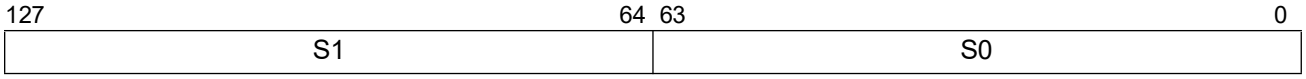
There are 128-bit and 256-bit versions of this instruction. Both versions have five operands:

VPERMIL2PD *dest, src1, src2, src3, m2z.*

The first four operands are either 128 bits or 256 bits wide, as determined by VEX.L. When the destination is an XMM register, bits above bit 127 of the corresponding ZMM/YMM register are cleared.

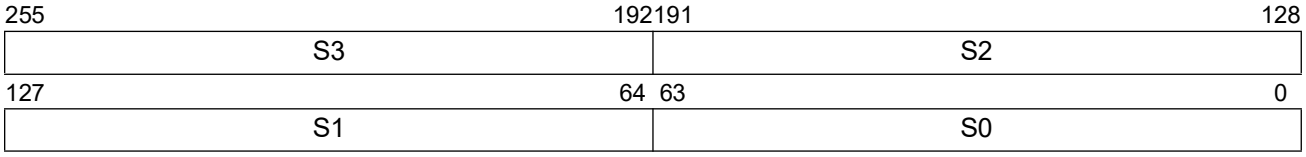
The third source operand is a selector that specifies how quadwords are copied or cleared in the destination. The selector contains one selector element for each quadword of the destination register.

Selector for 128-bit Instruction Form



The selector for the 128-bit instruction form is an octword composed of two quadword selector elements S0 and S1. S0 (the lower quadword) controls the value written to destination quadword 0 (bits [63:0]) and S1 (the upper quadword) controls the destination quadword 1 (bits [127:64]).

Selector for 256-bit Instruction Form



The selector for the 256-bit instruction form is a double octword and adds two more selector elements S2 and S3. S0 controls the value written to the destination quadword 0 (bits [63:0]), S1 controls the destination quadword 1 (bits [127:64]), S2 controls the destination quadword 2 (bits [191:128]), and S3 controls the destination quadword 3 (bits [255:192]).

The layout of each selector element is as follows:

Bits	Mnemonic	Description
[63:4]	—	Reserved, IGN
[3]	M	Match
[2:1]	Sel	Select
[0]	—	Reserved, IGN

[AMD Public Use]

The fields are defined as follows:

- Sel — Select. Selects the source quadword to copy into the corresponding quadword of the destination:

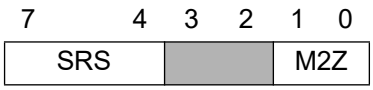
Sel Value	Source Selected for Destination Quadwords 0 and 1 (both forms)	Source Selected for Destination Quadwords 2 and 3 (256-bit form)
00b	*src1*[63:0]	*src1*[191:128]
01b	*src1*[127:64]	*src1*[255:192]
10b	*src2*[63:0]	*src2*[191:128]
11b	*src2*[127:64]	*src2*[255:192]

- M — Match bit. The combination of the Match bit in each selector element and the value of the M2Z field determines if the Select field is overridden. This is described below.

m2z immediate operand

The fifth operand is *m2z*. The assembler uses this 2-bit value to encode the M2Z field in the instruction. M2Z occupies bits [1:0] of an immediate byte. Bits [7:4] of the same byte are used to select one of 16 YMM/XMM registers. This dual use of the immediate byte is indicated in the instruction synopsis by the symbol “is5”.

The immediate byte is defined as follows.



Bits	Mnemonic	Description
[7:4]	SRS	Source Register Select
[3:2]	—	Reserved, IGN
[1:0]	M2Z	Match to Zero

Fields are defined as follows:

- SRS — Source Register Select. As with many other extended instructions, bits in the immediate byte are used to select a source operand register. This field is set by the assembler based on the operands listed in the instruction. See discussion in “*src2* and *src3* Operand Addressing” below.
- M2Z — Match to Zero. This field, combined with the M bit of the selector element, controls the function of the Sel field as follows:

M2Z Field	Selector M Bit	Value Loaded into Destination Quadword
0Xb	X	Source quadword selected by selector element Sel field.
10b	0	Source quadword selected by selector element Sel field.
10b	1	Zero
11b	0	Zero
11b	1	Source quadword selected by selector element Sel field.

[AMD Public Use]

src2 and *src3* Operand Addressing

In 64-bit mode, VEX.W and bits [7:4] of the immediate byte specify *src2* and *src3*:

- When VEX.W = 0, *src2* is a register or a memory location specified by ModRM.r/m and *src3* is a register specified by bits [7:4] of the immediate byte.
- When VEX.W = 1, s*rc2* is a register specified by bits [7:4] of the immediate byte and *src3* is a register or a memory location specified by ModRM.r/m.

In non-64-bit mode, bit 7 is ignored.

VPERMIL2PS Permute Two-Source Single-Precision Floating-Point

Copies a selected doubleword from one of two source operands to a selected doubleword of the destination or clears the selected doubleword of the destination. Values in a third source operand and an immediate two-bit operand control operation.

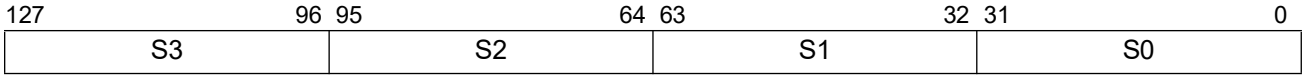
There are 128-bit and 256-bit versions of this instruction. Both versions have five operands:

VPERMIL2PS *dest, src1, src2, src3, m2z*

The first four operands are either 128 bits or 256 bits wide, as determined by VEX.L. When the destination is an XMM register, bits above bit 127 of the corresponding ZMM/YMM register are cleared.

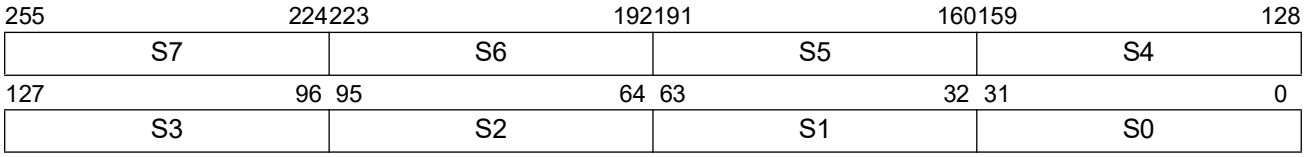
The third source operand is a selector that specifies how doublewords are copied or cleared in the destination. The selector contains one selector element for each doubleword of the destination register.

Selector for 128-bit Instruction Form



The selector for the 128-bit instruction form is an octword containing four selector elements S0–S3. S0 controls the value written to the destination doubleword 0 (bits [31:0]), S1 controls the destination doubleword 1 (bits [63:32]), S2 controls the destination doubleword 2 (bits [95:64]), and S3 controls the destination doubleword 3 (bits [127:96]).

Selector for 256-bit Instruction Form



The selector for the 256-bit instruction form is a double octword and adds four more selector elements S4–S7. S4 controls the value written to the destination doubleword 4 (bits [159:128]), S5 controls the destination doubleword 5 (bits [191:160]), S6 controls the destination doubleword 6 (bits [223:192]), and S7 controls the destination doubleword 7 (bits [255:224]).

The layout of each selector element is as follows.

Bits	Mnemonic	Description
[31:4]	—	Reserved, IGN
[3]	M	Match
[2:0]	Sel	Select

The fields are defined as follows:

[AMD Public Use]

- Sel — Select. Selects the source doubleword to copy into the corresponding doubleword of the destination:

Sel Value	Source Selected for Destination Doublewords 0, 1, 2 and 3 (both forms)	Source Selected for Destination Doublewords 4, 5, 6 and 7 (256-bit form)
000b	*src1*[31:0]	*src1*[159:128]
001b	*src1*[63:32]	*src1*[191:160]
010b	*src1*[95:64]	*src1*[223:192]
011b	*src1*[127:96]	*src1*[255:224]
100b	*src2*[31:0]	*src2*[159:128]
101b	*src2*[63:32]	*src2*[191:160]
110b	*src2*[95:64]	*src2*[223:192]
111b	*src2*[127:96]	*src2*[255:224]

- M — Match. The combination of the M bit in each selector element and the value of the M2Z field determines if the Sel field is overridden. This is described below.

m2z immediate operand

The fifth operand is *m2z*. The assembler uses this 2-bit value to encode the M2Z field in the instruction. M2Z occupies bits [1:0] of an immediate byte. Bits [7:4] of the same byte are used to select one of 16 YMM/XMM registers. This dual use of the immediate byte is indicated in the instruction synopsis by the symbol “is5”.

The immediate byte is defined as follows.

Bits	Mnemonic	Description
[7:4]	SRS	Source Register Select
[3:2]	—	Reserved, IGN
[1:0]	M2Z	Match to Zero

Fields are defined as follows:

- SRS — Source Register Select. As with many other extended instructions, bits in the immediate byte are used to select a source operand register. This field is set by the assembler based on the operands listed in the instruction. See discussion in “*src2* and *src3* Operand Addressing” below.
- M2Z — Match to Zero. This field, combined with the M bit of the selector element, controls the function of the Sel field as follows:

M2Z Field	Selector M Bit	Value Loaded into Destination Doubleword
0Xb	X	Source doubleword selected by Sel field.
10b	0	Source doubleword selected by Sel field.

[AMD Public Use]

M2Z Field	Selector M Bit	Value Loaded into Destination Doubleword
10b	1	Zero
11b	0	Zero
11b	1	Source doubleword selected by Sel field.

src2 and *src3* Operand Addressing

In 64-bit mode, VEX.W and bits [7:4] of the immediate byte specify *src2* and *src3*:

- When VEX.W = 0, *src2* is a register or a memory location specified by ModRM.r/m and *src3* is a register specified by bits [7:4] of the immediate byte.
- When VEX.W = 1, s*rc2* is a register specified by bits [7:4] of the immediate byte and *src3* is a register or a memory location specified by ModRM.r/m.

In non-64-bit mode, bit 7 is ignored.

[AMD Public Use]

VPERMILPD Permute Double-Precision

Within each 128-bit block, permute the 2 quadwords in that block. The selection of which quadword is the source for each quadword result is determined by a 1-bit selector.

For the forms of the instruction that have an immediate operand: The immediate byte contains up to 8 1-bit selectors in bits [0] through [7]. Two selector bits are used per 128-bit block: immediate bits [1:0], [3:2], [5:4], and [7:6] for the blocks at [127:0], [255:128], [383:256], and [511:384] respectively. Only 2 or 4 bits of the immediate byte will be used for XMM or YMM encoded forms of the instruction. The lower and higher of the 2 selector bits select quadwords for the destination block bits [63:0] and [127:64] respectively. The selector values 0b and 1b select the quadword from the source operand block bits [63:0] and [127:64] respectively.

For the forms of the instruction that do not have an immediate operand:

The 1-bit selectors are in bits [1] and [65] of the second source operand block (note that this is bit [1] of each quadword; bit [0] is unused), selecting a quadword for the destination block bits [63:0] and [127:64] respectively. The selector values 0b and 1b select the quadword from the first source operand block bits [63:0] and [127:64] respectively. Different selectors are used for every 128-bit block.

This extended-form instruction has 128-bit, 256-bit, and 512-bit encodings operating on 1, 2, and 4 blocks respectively:

XMM Encoding

There are two encodings, one for each selection method. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third XMM register. The first source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

There are two encodings, one for each selection method. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third YMM register. The first source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

There are two encodings, one for each selection method. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a third ZMM register. The first source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. The destination is a ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

[AMD Public Use]

VPERMILPS Permute Single-Precision

Within each 128-bit block, permute the 4 doublewords in that block. The selection of which doubleword is the source for each doubleword result is determined by a 2-bit selector.

For the forms of the instruction that have an immediate operand:

The immediate byte contains 4 2-bit selectors in bits [1:0], [3:2], [5:4] and [7:6], selecting a doubleword for the destination block bits [31:0], [63:32], [95:64], and [127:96] respectively. The selector values 00b, 01b, 10b, and 11b select the doubleword from the source operand block bits [31:0], [63:32], [95:64], and [127:96] respectively. The same selectors are used for every 128-bit block.

For the forms of the instruction that do not have an immediate operand:

The 2-bit selectors are in bits [1:0], [33:32], [65:64] and [97:96] of the second source operand block, selecting a doubleword for the destination block bits [31:0], [63:32], [95:64], and [127:96] respectively. The selector values 00b, 01b, 10b, and 11b select the doubleword from the first source operand block bits [31:0], [63:32], [95:64], and [127:96] respectively. Different selectors are used for every 128-bit block.

This extended-form instruction has 128-bit, 256-bit, and 512-bit encodings operating on 1, 2, and 4 blocks respectively:

XMM Encoding

There are two encodings, one for each selection method. The first source operand is an XMM register. The second source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third XMM register. The first source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is an XMM register. There is a third, immediate byte operand. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

There are two encodings, one for each selection method. The first source operand is a YMM register. The second source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third YMM register. The first source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a YMM register. There is a third, immediate byte operand. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

There are two encodings, one for each selection method. The first source operand is a ZMM register. The second source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a third ZMM register. The first source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The destination is a ZMM register. There is a third, immediate byte operand.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

VPERMPD Packed Permute Double-Precision Floating-Point

Copies selected quadwords from a 256/512-bit value located either in memory or a YMM/ZMM register to specific quadwords of the destination. For each quadword of the destination, selection of which quadword to copy from the source is specified by a selector field in an immediate byte or a YMM/ZMM register.

For the immediate form of this instruction, the selection of which quadword of the source/second operand to copy to each quadword of the destination is specified by four 2-bit selector fields in the third operand, an immediate byte. Bits [1:0] specify the index of the source quadword to be copied to the destination quadword 0, bits [3:2] for quadword 1, bits [5:4] for quadword 2, and bits [7:6] for quadword 3.

For 512-bit encodings, the immediate byte is reused as the selector for the upper 256-bits of the source and destination. Bits [1:0] specify which of the four quadwords in the upper 256-bits of the source to copy to quadword 4 of the destination. Bits [3:2] select for quadword 5, bits [5:4] for quadword 6, and bits [7:6] for quadword 7.

If a YMM/ZMM register is used as the selector, it is the second operand and specifies which of the quadwords from the source/third operand to copy to each quadword of the destination. For 256-bit encodings, the lowest 2 bits of each quadword in the selector are used as the index for the source. For 512-bit encodings, the lowest 3 bits of each quadword in the selector are the index.

The index value may be the same in multiple selectors. This results in multiple copies of the same source quadword being copied to the destination.

This instruction has 256-bit and 512-bit forms. There is no 128-bit form.

YMM Encoding

The destination is a YMM register and first operand. The source operand is either a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. If the selector is an immediate byte, it is the third operand and the source is second. If the selector is a YMM register, it is the second operand and the source is third.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination is a ZMM register and first operand. The source operand is either a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. If the selector is an immediate byte, it is the third operand and the source is second. If the selector is a ZMM register, it is the second operand and the source is third.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

[AMD Public Use]

VPERMPS Packed Permute Single-Precision Floating-Point

Copies selected doublewords from a 256/512-bit value located either in memory or a YMM/ZMM register to specific doublewords of the destination YMM/ZMM register.

The first source operand provides 3-bit selectors for 256-bit values or 4-bit selectors for 512-bit values. Each selector occupies the least-significant bits of a doubleword and specifies the index of the doubleword of the second source operand to be copied to the destination. The position of the doubleword containing the selector in the first source operand corresponds to the doubleword it controls in the destination.

The index value may be the same in multiple selectors. This results in multiple copies of the same source doubleword being copied to the destination.

This instruction has 256-bit and 512-bit forms. There is no 128-bit form.

YMM Encoding

The destination is a YMM register. The first source operand is a YMM register and the second source operand is either a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination is a ZMM register. The first source operand is a ZMM register and the second source operand is either a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

VPERMQ Packed Permute Quadword

Copies selected quadwords from a 256/512-bit value located either in memory or a YMM/ZMM register to specific quadwords of the destination. For each quadword of the destination, selection of which quadword to copy from the source is specified by a selector field in an immediate byte or a YMM/ZMM register.

For the immediate form of this instruction, the selection of which quadword of the source/second operand to copy to each quadword of the destination is specified by four 2-bit selector fields in the third operand, an immediate byte. Bits [1:0] specify the index of the source quadword to be copied to the destination quadword 0, bits [3:2] for quadword 1, bits [5:4] for quadword 2, and bits [7:6] for quadword 3.

For 512-bit encodings, the immediate byte is reused as the selector for the upper 256-bits of the source and destination. Bits [1:0] specify which of the four quadwords in the upper 256-bits of the source to copy to quadword 4 of the destination. Bits [3:2] select for quadword 5, bits [5:4] for quadword 6, and bits [7:6] for quadword 7.

If a YMM/ZMM register is used as the selector, it is the second operand and specifies which of the quadwords from the source/third operand to copy to each quadword of the destination. For 256-bit encodings, the lowest 2 bits of each quadword in the selector are used as the index for the source. For 512-bit encodings, the lowest 3 bits of each quadword in the selector are the index.

The index value may be the same in multiple selectors. This results in multiple copies of the same source quadword being copied to the destination.

This instruction has 256-bit and 512-bit forms. There is no 128-bit form.

YMM Encoding

The destination is a YMM register and first operand. The source operand is either a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. If the selector is an immediate byte, it is the third operand and the source is second. If the selector is a YMM register, it is the second operand and the source is third.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination is a ZMM register and first operand. The source operand is either a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. If the selector is an immediate byte, it is the third operand and the source is second. If the selector is a ZMM register, it is the second operand and the source is third.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

[AMD Public Use]

VPERMT2B

Each destination byte is copied from a byte in either the first source operand (table0) or the third source operand (table1) based on the value of a selector from a byte in the second source operand. The first source operand is the destination as well as the first source table. The third source operand is the second source table. The second source operand provides selectors that are 5-bits for 128-bit operations, 6-bits for 256-bit operations, or 7-bits for 512-bit operations. Each selector occupies the least-significant bits of a byte lane and specifies the source and index position of the byte to be copied to the destination. The position of the byte containing the selector corresponds to the byte it controls in the destination. The top bit of the selector selects the source of the data for that lane. A 0 selects the first source operand and a 1 selects the third source operand. The remaining bits of the selector select which byte lane in that source from which to copy the data. The selector may be the same in multiple lanes. This results in multiple copies of the same source byte being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit forms:

VPERMT2B

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination/first source operand is an XMM register. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination/first source operand is a YMM register. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination/first source operand is a ZMM register. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and do not support memory fault suppression.

VPERMT2D Permute Doubleword values from Two Tables Overwrite Table

Each destination word is copied from a word in either the first source operand (table0) or the third source operand (table1) based on the value of a selector from a word in the second source operand. The first source operand is the destination as well as the first source table. The third source operand is the second source table. The second source operand provides selectors that are 4-bits for 128-bit operations, 5-bits for 256-bit operations, or 6-bits for 512-bit operations. Each selector occupies the least-significant bits of a word lane and specifies the source and index position of the word to be copied to the destination. The position of the word containing the selector corresponds to the word it controls in the destination. The top bit of the selector selects the source of the data for that lane. A 0 selects the first source operand and a 1 selects the third source operand. The remaining bits of the selector select which word lane in that source from which to copy the data. The selector may be the same in multiple lanes. This results in multiple copies of the same source word being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit forms:

VPERMT2D

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination/first source operand is an XMM register. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination/first source operand is a YMM register. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination/first source operand is a ZMM register. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

VPERMT2PD Permute Double Precision Floating Point Values from Two Tables Overwrite Table

Each destination double precision floating point value is copied from a quadword in either the first source operand (table0) or the third source operand (table1) based on the value of a selector from a double precision floating point in the second source operand. The first source operand is the destination as well as the first source table. The third source operand is the second source table. The second source operand provides selectors that are 2-bits for 128-bit operations, 3-bits for 256-bit operations, or 4-bits for 512-bit operations. Each selector occupies the least-significant bits of a quadword lane and specifies the source and index position of the quadword to be copied to the destination. The position of the quadword containing the selector corresponds to the double precision floating point value it controls in the destination. The top bit of the selector selects the source of the data for that lane. A 0 selects the first source operand and a 1 selects the third source operand. The remaining bits of the selector select which quadword lane in that source from which to copy the data. The selector may be the same in multiple lanes. This results in multiple copies of the same source quadword being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit forms:

VPERMT2PD

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination/first source operand is an XMM register. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination/first source operand is a YMM register. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination/first source operand is a ZMM register. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 64-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and do not support memory fault suppression.

VPERMT2PS Permute Single Precision Floating Point Values from Two Tables Overwrite Table

Each destination single precision floating point value is copied from a doubleword in either the first source operand (table0) or the third source operand (table1) based on the value of a selector from a single precision floating point in the second source operand. The first source operand is the destination as well as the first source table. The third source operand is the second source table. The second source operand provides selectors that are 3-bits for 128-bit operations, 4-bits for 256-bit operations, or 5-bits for 512-bit operations. Each selector occupies the least-significant bits of a doubleword lane and specifies the source and index position of the doubleword to be copied to the destination. The position of the doubleword containing the selector corresponds to the single precision floating point value it controls in the destination. The top bit of the selector selects the source of the data for that lane. A 0 selects the first source operand and a 1 selects the third source operand. The remaining bits of the selector select which doubleword lane in that source from which to copy the data. The selector may be the same in multiple lanes. This results in multiple copies of the same source doubleword being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit forms:

VPERMT2PS

The extended form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination/first source operand is an XMM register. The second source operand is an XMM register. The third source operand is an XMM register, a 128-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The destination/first source operand is a YMM register. The second source operand is a YMM register. The third source operand is a YMM register, a 256-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination/first source operand is a ZMM register. The second source operand is a ZMM register. The third source operand is a ZMM register, a 512-bit memory location, or (for EVEX encodings) a broadcast 32-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and do not support memory fault suppression.

VPERMW Packed Permute Words

Copies selected words from a 128/256/512-bit value located either in memory or a XMM/YMM/ZMM register to specific words of the destination XMM/YMM/ZMM register.

The first source operand provides selectors that are 3-bits for 128-bit values, 4-bits for 256-bit values, or 5-bits for 512-bit values. Each selector occupies the least-significant bits of a word and specifies the index of the word of the second source operand to be copied to the destination. The position of the word containing the selector in the first source operand corresponds to the word it controls in the destination.

The index value may be the same in multiple selectors. This results in multiple copies of the same source word being copied to the destination.

This instruction has 128-bit, 256-bit, and 512-bit forms:

XMM Encoding

The destination is a XMM register. The first source operand is a XMM register and the second source operand is either a XMM register or a 128-bit memory location.

Bits above bit 127 of the ZMM/YMM register that corresponds to the destination are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location.

Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The destination is a ZMM register. The first source operand is a ZMM register and the second source operand is either a ZMM register or a 512-bit memory location.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and do not support memory fault suppression.

VPEXPANDB Expand Compressed Bytes

Select compressed (contiguous) byte elements from the least significant elements of the source operand. The number of elements selected is determined by the number of “1” bits in the K mask register. Expand the selected elements starting at the least significant bit and element, one source element assigned to an element in the destination if the associated mask register bit is “1”. Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select and expand elements of the source as mentioned above, and then the original mask value is used to write the destination. When the source operand is memory, the number of “1” bits in the K mask is used to read only the selected elements as one block and memory fault suppression is supported. The effective mask for the memory read is a compressed version of the K mask, with all of the “1” bits shifted down to the lowest bits. Normal merge masking and zero masking are supported when writing the destination register. For example, when expanding up to 64 byte elements from a ZMM register or memory, if the K mask register is hex 80000000_0b000002, the mask bits are “1” for elements 63, 27, 25, 24, and 1. Since there are 5 “1” bits in the mask value, 5 elements are read from the source operand (register or memory). These elements are then expanded, or distributed, into elements 1, 24, 25, 27, and 63 of the destination using the K mask (of course, none of these elements are masked off since their mask bits are all “1”). The other elements of the destination all have a “0” mask bit and are merge-masked or zero masked according to the EVEX.z bit as usual.

The VPCOMPRESSB instruction is effectively the opposite of the VPEXPANDB instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 8-bit element and support memory fault suppression.

[AMD Public Use]

VPEXPANDD Expand Compressed Doublewords

Select compressed (contiguous) doubleword elements from the least significant elements of the source operand. The number of elements selected is determined by the number of “1” bits in the K mask register. Expand the selected elements starting at the least significant bit and element, one source element assigned to an element in the destination if the associated mask register bit is “1”. Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select and expand elements of the source as mentioned above, and then the original mask value is used to write the destination. When the source operand is memory, the number of “1” bits in the K mask is used to read only the selected elements as one block and memory fault suppression is supported. The effective mask for the memory read is a compressed version of the K mask, with all of the “1” bits shifted down to the lowest bits. Normal merge masking and zero masking are supported when writing the destination register. See the VPEXPANDB instruction for an example of how the VPEXPANDx instructions work. The VPCOMPRESSD instruction is effectively the opposite of the VPEXPANDD instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 32-bit element and support memory fault suppression.

[AMD Public Use]

VPEXPANDQ Expand Compressed Quadwords

Select compressed quadword elements from the least significant elements of the source operand. The number of elements selected is determined by the number of "1" bits in the K mask register. Expand the selected elements starting at the least significant bit and element, one source element assigned to an element in the destination if the associated mask register bit is "1". Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select and expand elements of the source as mentioned above, and then the original mask value is used to write the destination. When the source operand is memory, the number of "1" bits in the K mask is used to read only the selected elements as one block and memory fault suppression is supported. The effective mask for the memory read is a compressed version of the K mask, with all of the "1" bits shifted down to the lowest bits. Normal merge masking and zero masking are supported when writing the destination register. See the VPEXPANDB instruction for an example of how the VPEXPANDx instructions work. The VPCOMPRESSQ instruction is effectively the opposite of the VPEXPANDQ instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The first source operand is a ZMM register. The second source operand is a ZMM register or a 512-bit memory location. The destination is a third ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 64-bit element and support memory fault suppression.

VPEXPANDW Expand Compressed Words

Select compressed (contiguous) word elements from the least significant elements of the source operand. The number of elements selected is determined by the number of “1” bits in the K mask register. Expand the selected elements starting at the least significant bit and element, one source element assigned to an element in the destination if the associated mask register bit is “1”. Note that the K mask register specified by EVEX.aaa does not operate exactly as it normally does for most instructions. Instead it is used to select and expand elements of the source as mentioned above, and then the original mask value is used to write the destination. When the source operand is memory, the number of “1” bits in the K mask is used to read only the selected elements as one block and memory fault suppression is supported. The effective mask for the memory read is a compressed version of the K mask, with all of the “1” bits shifted down to the lowest bits. Normal merge masking and zero masking are supported when writing the destination register. See the VPEXPANDB instruction for an example of how the VPEXPANDx instructions work. The VPCOMPRESSW instruction is effectively the opposite of the VPEXPANDW instruction.

This instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The source operand is an XMM register or a 128-bit memory location. The destination is a second XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register or a 256-bit memory location. The destination is a second YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination are cleared.

ZMM Encoding

The source operand is a ZMM register or a 512-bit memory location. The destination is a second ZMM register.

The EVEX encoded versions of this instruction write to the destination based on the supplied k mask per 16-bit element and support memory fault suppression.

[AMD Public Use]

VPGATHERDD Conditionally Gather Doublewords, Doubleword Indices

Conditionally loads four, eight, or sixteen doubleword (32-bit) values from memory using VSIB addressing with doubleword indices

The VEX encoding of the instructions is of the form:

VPGATHERDD dest, mem32[vm32x/y], mask

The EVEX encoding of the instruction is of the form:

VPGATHERDD dest {k1}, mem32[vm32x/y/z]

Loading of each element of the destination register is conditional based on the value of the corresponding element of the mask operand. For VEX encodings, if the most-significant bit of the ith element of the mask is set, the ith element of the destination is loaded from memory using the ith address of the array of effective addresses calculated using VSIB addressing. For EVEX encodings, the bit of the k-mask corresponding to the lane being set allows for the lane to be loaded from memory using the corresponding effective address calculated using VSIB addressing.

The index register is treated as an array of signed 32-bit values. Doubleword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 8 for a discussion of the VSIB addressing mode.

There are VEX-encoded and EVEX encoded forms of the instruction:

VEX-encoded Forms

The destination is an XMM or YMM register. The first source operand is up to eight 32-bit values located in memory. The second source operand (the mask) is an XMM or YMM register. The index vector is up to eight doublewords of an XMM or YMM register.

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The destination is an XMM register. The first source operand is up to four 32-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the four doublewords of an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 127 of the YMM/ZMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is up to eight 32-bit values located in memory. The second source operand (the mask) is a YMM register. The index vector is the eight doublewords of an XMM register. Bits above bit 255 of the ZMM register that corresponds to the destination and bits above bit 255 of the ZMM register that corresponds to the second source (mask) operand are cleared.

[AMD Public Use]

EVEX-encoded Forms

The destination is an XMM, YMM, or ZMM register, updated according to a mask register 'k1'. The source operand is up to 16 32-bit values located in memory. The index vector is up to 16 doublewords of an XMM, YMM, or ZMM register.

VPGATHERDD

The EVEX-encoded form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination is an XMM register. The source operand is up to four 32-bit values located in memory. The index vector is the four doublewords of an XMM register. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 3 of the k-mask register are cleared.

YMM Encoding

The destination is a YMM register. The source operand is up to eight 32-bit values located in memory. The index vector is the eight doublewords of a YMM register. Bits above bit 255 of the ZMM register that corresponds to the destination and bits above bit 7 of the k-mask register are cleared.

ZMM Encoding

The destination is a ZMM register. The source operand is up to 16 32-bit values located in memory. The index vector is the 16 doublewords of a YMM register. Bits above bit 15 of the k-mask register are cleared.

[AMD Public Use]

VPGATHERDQ Conditionally Gather Quadwords, Doubleword Indices

Conditionally loads 2, 4, or 8 quadword (64-bit) values from memory using VSIB addressing with doubleword indices

The VEX encoding of the instructions is of the form:

VPGATHERDQ dest, mem64[vm32x], mask

The EVEX encoding of the instruction is of the form:

VPGATHERDQ dest {k1}, mem64[vm32x/y]

Loading of each element of the destination register is conditional based on the value of the corresponding element of the mask operand. For VEX encodings, if the most-significant bit of the ith element of the mask is set, the ith element of the destination is loaded from memory using the ith address of the array of effective addresses calculated using VSIB addressing. For EVEX encodings, the bit of the k-mask corresponding to the lane being set allows for the lane to be loaded from memory using the corresponding effective address calculated using VSIB addressing.

The index register is treated as an array of signed 32-bit values. Quadword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 8 for a discussion of the VSIB addressing mode.

There are VEX-encoded and EVEX encoded forms of the instruction:

VEX-encoded Forms

The destination is an XMM or YMM register. The first source operand is up to four 64-bit values located in memory. The second source operand (the mask) is an XMM or YMM register. The index vector is up to four doublewords of an XMM register.

The VEX-encoded form of the instruction has 128-bit and 256-bit encoding:

XMM Encoding

The destination is an XMM register. The first source operand is up to two 64-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the two low-order doublewords of an XMM register; the two high-order doublewords of the index register are not used. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 127 of the YMM/ZMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is up to four 64-bit values located in memory. The second source operand (the mask) is a YMM register. The index vector is the four doublewords of an XMM register. Bits above bit 255 of the ZMM register that corresponds to the destination and bits above bit 127 of the YMM/ZMM register that corresponds to the second source (mask) operand are cleared.

[AMD Public Use]

EVEX-encoded Forms

The destination is an XMM, YMM, or ZMM register, updated according to a mask register 'k1'. The source operand is up to eight 64-bit values located in memory. The index vector is up to eight doublewords of an XMM or YMM register.

VPGATHERDQ

The EVEX-encoded form of the instruction has 128-bit, 256-bit, and 512-bit encodings:

XMM Encoding

The destination is an XMM register. The source operand is up to two 64-bit values located in memory. The index vector is the two low-order doublewords of an XMM register; the two high-order doublewords of the index register are not used. Bits above bit 127 of the YMM/ZMM register that corresponds to the destination and bits above bit 1 of the k-mask register are cleared.

YMM Encoding
